CONTENTS

CHAPTER 1

Iron in Antiquity	1
Prehistoric and ancient use of iron. Meteoric iron. Telluric (native) iron. Man-made iron. Archeological evidence. Products of ancient iron smelting. Early cast iron. Bibliography.	

CHAPTER 2

Some Fundamental Principles of Chemistry and Physics	4
---	---

Part 1. The Composition, Structure and Properties of Matter

SECTION 1: THE RELATION OF METALLURGY TO PHYSICS AND CHEMISTRY. SECTION 2: COMPOSITION OF MATTER. The nature of matter. Mixtures, compounds and chemical elements. Symbols of the chemical elements. Broad classification of chemical elements. Atoms and molecules. Atomic and molecular weights. **SECTION 3: THE STRUCTURE OF MATTER.** Atomic structure. The atomic nucleus. The electronic system. Periodicity of the elements. Isotopes. Summary on atomic structure. Physical, chemical and nuclear changes. **SECTION 4: CRYSTALLOGRAPHY. SECTION 5: FUNDAMENTAL CHARACTERISTICS OF MATTER.** Length, mass and time. States of matter. Changes of state. Vapor pressure. Electrical conductivity. Density. Specific gravity. Elasticity. Plasticity. Tensile strength. Hardness. Viscosity. Specific heat and heat capacity. Thermal expansion. Thermal conductivity.

Part 2. Fundamental Principles of Chemistry

SECTION 1: BRANCHES OF CHEMISTRY. SECTION 2: CHEMICAL FORMULAS AND REACTIONS. Chemical formulas of compounds. Molecules of elements. Chemical equations. Heat of reaction. Kinds of reactions. **SECTION 3: KINDS OF CHEMICAL COMPOUNDS.** Acids. Bases. Salts. Nonelectrolytes. Anhydrides. **SECTION 4: VALENCE AND VALENCE NUMBERS. SECTION 5: RADICALS. SECTION 6: IONS AND ELECTROLYSIS. SECTION 7: FUNDAMENTAL LAWS OF CHEMICAL CHANGE.** Law of constancy of nature. Law of conservation of matter. The law of definite proportions. Law of multiple proportions. Qualitative considerations. **SECTION 8: SOLUTIONS.** Distribution coefficient. Vapor pressure of solutions. Phase or constitution diagrams. Time-temperature curves. Examples of typical binary solutions. Ternary systems. **SECTION 9: CHEMICAL NOMENCLATURE.** General principle. Terminology of binary compounds. Terminology of ternary compounds. Terminology of acids. Terminology of bases. Terminology of salts. Neutralization. Hydroxyl and hydrogen ions. **SECTION 10: CHEMICAL CALCULATIONS.** Kinds of problems. Problems involving weight. Problems involving volume only. Problems involving both weight and volume. Mol fraction. **SECTION 11: SOME ELEMENTS COMMON IN STEELMAKING.** Oxygen. Hydrogen. Sulphur. Carbon. Silicon. Nitrogen. Phosphorus. Calcium and magnesium. Aluminum. Chromium. Manganese. Iron.

Part 3. Fundamentals of Physics

SECTION 1: INTRODUCTORY. SECTION 2: ENERGY, FORCE, WORK AND POWER. Nature of energy. Potential vs. kinetic energy. Forms of potential energy. Conversion of energy. Conservation of energy. Force. Work. Power. Transmission of energy. **SECTION 3: HEAT.** Nature of heat. Temperature. Thermometry and pyrometry. Measurement of heat. Heat vs. changes in state of matter. Conversion of heat into mechanical and electrical energy. Effects of temperature on physical properties. Heat flow. **SECTION 4: MAGNETISM AND MAGNETIC FIELDS.** Natural magnets. Artificial magnets. Magnetic fields. Earth's magnetic field. Magnetic field strength. Magnetic induction. Permeability. Retentivity. Reluctance. Theory of magnetism. **SECTION 5: ELECTROSTATICS.** Nature of electrostatic charges. Induced electrostatic charges. Electric discharge. Static electricity and electricity in motion. **SECTION 6: CHEMICAL GENERATION OF ELECTRIC**

THE MAKING, SHAPING AND TREATING OF STEEL

CURRENT. SECTION 7: POTENTIAL, CURRENT, RESISTANCE. SECTION 8: FLOW OF DIRECT CURRENT IN CONDUCTORS. Ohm's Law. Resistance in series. Resistances in parallel. Law of divided circuits. **SECTION 9: ELECTRO-MAGNETISM.** Magnetic fields and electric currents. **SECTION 10: ELECTRIC ENERGY AND POWER. SECTION 11: ELECTROMAGNETIC INDUCTION.** Self-induction. Laws of electromagnetic induction. **SECTION 12: MECHANICAL GENERATION OF ELECTRIC CURRENT.** Alternating-current generator. Direct-current generator. **SECTION 13: CHARACTERISTICS OF ALTERNATING CURRENT.** Frequency. Polyphase current. Effective values of alternating current and voltage. Impedance. Power factor. **SECTION 14: PRINCIPLES OF MOTORS.** Direct-current motor. Alternating-current motor. **SECTION 15: PRINCIPLES OF TRANSFORMERS. SECTION 16: CURRENT RECTIFICATION.** Motor-generator sets. Frequency changers. Mercury-arc rectifiers.

CHAPTER 3

Fuels and Combustion. 51

SECTION 1: INTRODUCTORY. SECTION 2: CLASSIFICATION OF FUELS. The classification of fuels. Importance of each class. **SECTION 3: PRINCIPLES OF COMBUSTION.** Calorific value of fuels. Thermal capacity, heat capacity and specific heat. Gas laws. Combustion calculations. **SECTION 4: HEAT FLOW.** Conduction. Convection. Radiation. **SECTION 5: SOLID FUELS AND THEIR UTILIZATION.** Coal resources. Origin and composition of coal. Chemical composition and coal classification. Mining of coal. Continuous mining. Coal preparation. Carbonization of coal. Combustion of solid fuels. Pulverized coal. **SECTION 6: LIQUID FUELS AND THEIR UTILIZATION.** Origin, composition and distribution of petroleum. Grades of petroleum used as fuels. Properties and specification of liquid fuels. Combustion of liquid fuels. Liquid-fuel burners. **SECTION 7: GASEOUS FUELS AND THEIR UTILIZATION.** Natural gas. Manufactured gases. Manufacture of producer gas. Manufacture of water gas. Special gas processes. By-product gaseous fuels. Blast-furnace gas. Coke-oven gas. Use of various gaseous fuels in the steel industry. Combustion of various gaseous fuels. **SECTION 8: FUEL ECONOMY.** Efficiency of heat utilization in steel plants. Means employed for heat conservation. Fuel-air proportioning. Oxygen enrichment of combustion air. Furnace pressure control. Automatic temperature control. Regenerators and recuperators. Waste-heat boilers. Insulation. **Bibliography.**

CHAPTER 4

Metallurgical Coke Production. 90

SECTION 1: INTRODUCTORY. Selection and preparation of coal for coking. Kinds of coke. Factors controlling properties of metallurgical coke. Methods of manufacturing metallurgical coke. **SECTION 2: THE BEEHIVE PROCESS FOR CARBONIZING COAL.** Construction of ovens. Waste-heat system. Charging. Coking process. Watering and drawing. Present status of beehive process. **SECTION 3: THE BY-PRODUCT PROCESS FOR CARBONIZING COAL.** Modern types of by-product ovens in the United States. The Koppers oven. The Koppers-Becker oven. The Wilputte oven. The Semet-Solvay oven. **SECTION 4: CONSTRUCTION AND OPERATION OF BY-PRODUCT OVENS.** Coking chamber. Heating system. Oven doors. Gas-collecting system. **SECTION 5: ACCESSORY OVEN EQUIPMENT.** Coal-storage bins and charging larries. Pusher-side equipment. Coke-side equipment. Quenching station. Instrumentation and control. **SECTION 6: COKE SCREENING AND HANDLING.** Coke wharf. Conveyor system for coke. Screening and crushing. Storage and shipping. **SECTION 7: LIMITATIONS AND FUTURE OF BY-PRODUCT COKING.**

CHAPTER 5

Recovery of Coal Chemicals. 113

SECTION 1: INTRODUCTORY. Chemical nature of coal. Products of coal carbonization. **SECTION 2: COLLECTION OF VOLATILE PRODUCTS FROM OVENS.** Collecting main and suction main. **SECTION 3: RECOVERY OF CRUDE COAL TAR.** Hot tar drain tank. Primary cooler. Tar extractor. **SECTION 4: RECOVERY OF AMMONIA AS AMMONIUM SULPHATE.** Semi-direct process. Ammonia still. Reheater. Ammonia absorber. Saturator. **SECTION 5: RECOVERY OF PHENOL.** Vapor-recirculation process. Solvent extraction process. **SECTION 6: RECOVERY AND REFINING OF PYRIDINE BASES.** Batch-type recovery process for pyridine bases. Refining of pyridine bases. **SECTION 7:**

RECOVERY OF COKE-OVEN LIGHT OIL. Light oil. Light-oil recovery process. Final cooler. Wash-oil scrubber. Debenzolization of wash oil. **SECTION 8: REFINING OF COKE-OVEN LIGHT OIL.** Acid washing. Fractional distillation. Batch still operation. Continuous still operation. Control of distillation processes. Types of refining processes. Semi-continuous process. Continuous process. **SECTION 9: REFINING OF COAL TAR.** Distillation of tar. Pyridine sulphate recovery. **Tar-acid recovery.** Washing. Rectifying. Springing. Batch rectifier. Batch carbonating, or springing system. Lime kiln. Batch caustic system. Continuous causticizing system. Rotary kiln. **Tar-acid refining.** Horizontal pot still. Vertical pot still. Steam-heated vacuum batch still. **Naphthalene recovery.** **SECTION 10: USES OF COKE, COKE-OVEN GAS AND COAL CHEMICALS.** Metallurgical coke. Fuel gas. Ammonium sulphate. Phenol. Ortho cresol. Meta-para cresol. Xylenes. Naphthalene. Creosote oil. Pyridine bases. Pitch-tar mixture. Forerunnings. Pure benzene. Motor benzene. Pure toluene. Crude heavy solvent. Refined heavy solvent.

CHAPTER 6

Iron Ores 139

SECTION 1: ORES AND THE IRON-BEARING MINERALS. Minerals and ores. The iron-bearing minerals. Magnetite group. Hematite group. Limonite or brown ore group. The carbonate group. The silicate group. Distribution and supply of iron ores. Geologic range of iron ores. Formations associated with iron ores. Origin of iron ores. **SECTION 2: VALUATION OF ORES.** The mineralogical make-up of iron ores. Factors in the valuation of ores. Composition. Accessibility. **SECTION 3: IRON ORE DEPOSITS OF THE UNITED STATES.** The main producing districts. **SECTION 4: THE BIRMINGHAM DISTRICT.** Location, geology and general description. Hematite. Limonite. Beneficiation of red ore (hematite). Sinter plant. **SECTION 5: WESTERN IRON ORES.** Origin of the Utah ores. General geology of the Utah mining districts. Occurrence of the ores "in situ." Ore types. Development and mining practice. Ore reserves of Utah. **SECTION 6: THE LAKE SUPERIOR DISTRICT.** Location. Importance. General geology. **The Marquette range. The Menominee range. The Gogebic range. The Vermillion range. The Mesabi range. The Cuyuna range.** **SECTION 7: MINING THE LAKE ORES.** Prospecting and exploration. Drill exploration. Methods of mining. **Open-pit mining.** Haulage systems. Drilling and blasting. Waste dumps. Scramming. Drainage. Transporting and sampling of ores. Crushing and screening ore. **Open-pit mining equipment.** Shovels. Locomotives. Stripping cars. Tracks. Belt conveyors. Electric power distribution. Shops. Safety. Advantages of open-pit mining. Beneficiation of ores. **Underground mining.** Importance. Underground haulage. Mining methods. Caving methods. Open-stoping methods. Grading the ores. Transporting the ores. Mining and grading in winter. **Bibliography.**

CHAPTER 7

Fluxes and Slags 172

SECTION 1: FLUXES. Function of fluxes. Chemistry of fluxes. Acid fluxes. Basic fluxes. Alumina. Neutral fluxes. Sources of fluxing materials. Preparation of fluxes for use. **SECTION 2: SLAGS.** Metallurgical functions of slags. Secondary metallurgical uses of slag. **SECTION 3: SLAGS AS BY-PRODUCTS.** Specific uses of blast-furnace slag. **SECTION 4: FUNCTIONS OF SLAGS AS SOIL CONDITIONERS.** **SECTION 5: MANUFACTURE OF PORTLAND CEMENT.** Raw materials. Dry and wet processes. The burning (calcining) operation. **Bibliography.**

CHAPTER 8

Refractories 180

SECTION 1: Classification of Refractories. **A. Siliceous Group.** Quartzite. Sandstone. Mica schist. Siliceous fireclays. **B. Fireclay Group.** Plastic fireclay. Flint fireclay. Nodular fireclay. Kaolins. **C. High-Alumina Group.** Bauxite and diaspore. Sillimanite, andalusite, and kyanite. **D. Magnesium-Silicate Group.** **E. Magnesia-Lime Group.** **F. Chromite Group.** **G. Carbon Group.** Preparation of Refractories. **SECTION 2: A. MASSIVE REFRACTORIES.** Raw state. Burned products. Chemically bonded products (basic brick). Refractory concrete products. Electrocast products. **B. GRANULAR REFRACTORIES.** Raw state. Fired products. **C. FINELY DIVIDED OR PULVERIZED PRODUCTS.** Raw state. Processed products. **SECTION 3: PHYSICAL AND CHEMICAL CHARACTERISTICS OF RE-**

THE MAKING, SHAPING AND TREATING OF STEEL

REFRACTORIES AND THEIR APPLICATION TO MEET SERVICE CONDITIONS. Fusion or softening temperature. Porosity and permeability. Bulk density and true specific gravity. Thermal expansion and volume changes. Cold strength. Strength and behavior under load at high temperatures. Heat capacity and thermal conductivity. Resistance to thermal shock (spalling). Abrasion resistance. SECTION 4: REACTIONS AT ELEVATED TEMPERATURES. SECTION 5: SELECTION AND TESTING OF STEEL-PLANT REFRACTORIES. SECTION 6: SPECIFIC USES OF REFRACTORIES IN STEEL PLANTS. Blast furnaces and stoves. Hot-metal mixers. Basic open-hearth furnaces. Basic electric-arc steel-making furnaces. Pouring-pit refractories. Soaking pits. Heating furnaces. Bibliography.

CHAPTER 9

Addition Agents Used in Steelmaking. 202

Definitions. Use of addition agents. Storage facilities for addition agents. **Compositions of Common Addition Agents.** Ferromanganese. Silicomanganese. Spiegeleisen. Ferrosilicon. Ferrochromium. Ferrovanadium. Ferromolybdenum. Ferrotitanium. Zirconium. Ferrophosphorus. Nickel. Copper. Aluminum. Cobalt. Ferrocolumbium. Ferroselenium. Tantalum. Tungsten. Sulphur. Carbon. "Hardenableity intensifiers."

CHAPTER 10

Scrap for Steelmaking. 204

Types and sources of scrap. Home scrap. Purchased scrap. Physical preparation of scrap. Chemical composition of scrap.

CHAPTER 11

The Manufacture of Sponge Iron and Wrought Iron. 206

SECTION 1: SPONGE IRON. SECTION 2: DIRECT PROCESSES FOR MAKING WROUGHT IRON. Historical background of direct processes. The Catalan process. The American bloomery. The stuckofen. SECTION 3: INDIRECT PROCESSES FOR MAKING WROUGHT IRON. Walloon process. South Wales process. Lancashire process. Hand puddling processes. SECTION 4: CONSTRUCTION OF THE HAND-PUDDLING FURNACE. SECTION 5: OPERATION OF THE HAND-PUDDLING FURNACE. SECTION 6: ROLLING OF HAND-PUDDLED WROUGHT IRON. Shingling or squeezing the ball. Rolling the squeezed ball. Variables in the muck bar. Busheling. Piling. Double refining. SECTION 7: REACTIONS AND PROCESS LOSSES IN HAND-PUDDLING. SECTION 8: MECHANICAL PUDDLING. Principles of mechanical puddling. SECTION 9: THE ASTON PROCESS. SECTION 10: COMPOSITION, STRUCTURE AND PROPERTIES OF WROUGHT IRON. Chemical composition of wrought iron. Macroscopic structure of wrought iron. Microscopic structure of wrought iron. Mechanical properties of wrought iron.

CHAPTER 12

The Manufacture of Pig Iron. 220

SECTION 1: HISTORY, PRODUCTION AND KINDS OF PIG AND CAST IRON. The importance of pig iron. Kinds and grades of pig iron. Chief metallic products of the blast furnace. SECTION 2: OUTLINE OF THE BLAST-FURNACE PROCESS. Furnace input and output. Functions of the charged materials. Parts of a blast-furnace plant. SECTION 3: CONSTRUCTION OF THE FURNACE PROPER. Foundation. Columns and base plates. Mantle. Shell. Hearth. Bosh. In-walls. Thick-wall type. Intermediate, or semi-thin, wall type. Thin-wall type. Relationship of furnace dimensions. Furnace linings. Water troughs. Top. Hoisting appliances. Top appliances for distributing the stock. Top openings. General considerations for top construction. SECTION 4: CONSTRUCTION OF FURNACE AUXILIARIES. Stoves. Dustcatcher and gas mains. Gas-cleaning plants. Wash-water disposal. Sintering plant. Cast house. Iron disposal. Slag disposal. Handling ore from vessel. Car dumper. Ore yard and ore bridges. Trestle and stockhouse. Blowers, boilers, pump houses, etc. Instrumentation and control. SECTION 5: OPERATION OF THE FURNACE. Drying. Filling. Lighting. Heating the bottom. Heating the stoves. Blast control. Flushing and casting. Care of runners. Sampling the iron. Changing stoves. Charging the furnace. Fanning. Furnace irregularities. Distribution of stock. Breakouts. Copper losses. Variables

in furnace control. Banking. Blowing out. **SECTION 6: CHEMISTRY OF THE PROCESS.** Reactions of oxygen and carbon. Carbon in pig iron. Silicon. Manganese. Phosphorus. Disposition of sulphur. Action of calcium and magnesium. Action of aluminum. Action of less abundant elements. Reactions within the furnace. Tracing the materials through the furnace. Conditions affecting silicon and sulphur in the metal. **SECTION 7: THE BLAST-FURNACE BURDEN.** Burdening the furnace. Outline of a method for solving a burdening problem. The burden sheet. **SECTION 8: DRY BLAST, OXYGEN ENRICHMENT, PRESSURE OPERATION, BENEFICIATED MATERIALS.** Dry blast. Oxygen enrichment. Pressure operation. Beneficiated materials. **Bibliography.**

CHAPTER 13

Early Processes for Conversion of Iron into Steel. 261

SECTION 1: PROBABLE ANCIENT METHODS. SECTION 2: THE CEMENTATION PROCESS. SECTION 3: THE CRUCIBLE PROCESS: Manufacture of the crucibles. The crucible melting furnace. Charging the crucibles. Stages of the crucible process. Casting. Stripping and inspecting the ingots. Chemistry of the crucible process: **SECTION 4: MODERN STEELMAKING PROCESSES.**

CHAPTER 14

The Pneumatic Steelmaking Processes. 266

SECTION 1: INTRODUCTORY. General principles of steelmaking. Principles and types of pneumatic processes. Historical development. Characteristics of pneumatic steels. **SECTION 2: THE BOTTOM-BLOWN ACID (BESSEMER) PROCESS.** Plant layout. The air blast. Bottom house. The converter or vessel. Refractory lining. Bottom design. Life of bottoms. Cupolas. Hot-metal mixer. Sequence of operations. Ladles. Ingot molds. The stripper. Chemistry of the acid-Bessemer blow. Phosphorus and sulphur control. End-point evaluation. Temperature control. Oxygen-enriched blast. Blowing time and quality. Deoxidation of acid-Bessemer steel. Carbon deoxidation. Manganese and silicon additions. Economic considerations. Investment costs. Scrap market conditions. Metal losses. Possible future trends. **SECTION 3: THE BASIC BESSEMER OR THOMAS PROCESS.** Historical. Composition of pig iron for basic process. Principal facilities. Mixer. Blowing equipment. The converter or vessel. Bottom design. Lining and bottom life. Sequence of operations. Chemistry of the Thomas process. Thermal requirements. Temperature control. Deoxidation reactions. Nitrogen control. Control of end point. **SECTION 4: THE SURFACE-SIDE-BLOWN ACID PROCESS.** The converter and its auxiliaries. Sequence of operations. Oxidation reactions. Temperature control. Deoxidation reactions. Nitrogen control. Control of the end point. Oxygen and oxygen-enriched air for blast. **SECTION 5: THE OXYGEN-BLOWN BASIC STEELMAKING PROCESSES.** Mixers and blowing equipment. The converter or vessel. Sequence of operations. Temperature control. Deoxidation reactions. Nitrogen and end-point control. **Bibliography.**

CHAPTER 15

The Open-Hearth Processes. 287

SECTION 1: SOME GENERAL FEATURES OF THE SIEMENS PROCESS. Early history of the process. Principles of Siemens' pig and ore process. Mechanical changes and improvements in the Siemens process. Metallurgical improvements. Advantages of the Siemens process. The open-hearth process in the United States. **SECTION 2: BASIC OPEN-HEARTH PLANT LAYOUT.** Layout of the main furnace building. Charging side. Pouring floor or pit side. Stockyard. Leanto. Trackage. Mold yard. Miscellaneous facilities. **SECTION 3: FURNACE CONSTRUCTION.** Description. Parts of the open-hearth furnace and their arrangement. The furnace proper. The basic hearth. Burned-in grain magnesite bottoms. Rammed magnesite or plastic chromite sub-hearths with burned-in working hearth. All-rammed bottoms. Basic hearth tap hole. The acid hearth. Acid hearth tap hole. Making the acid bottom. Front walls and doors. Back wall. Main roof. Port ends. Slag pockets. Regenerator (checker) chambers. Forced draft fans. Flues. Valves. Waste-heat boilers. Stacks. **SECTION 4: OPERATION OF A BASIC OPEN HEARTH.** Purifying the metal. Furnace attendants and their duties. Charging. "Fifty-fifty" practice. High molten pig iron practice. Melting down the charge. Melting down after molten pig iron addition. Working or refining period. Duration of various periods in production of basic open-hearth steel. **SECTION 5: TAPPING AND POURING.** Tapping. Ladles. Ladle nozzles. Stopper-

THE MAKING, SHAPING AND TREATING OF STEEL

rod assembly. Pouring. Turn dish or basket pouring. Bottom pouring. Sampling the steel. Ingot molds. Ingot height. **SECTION 6: KEEPING THE BASIC OPEN-HEARTH FURNACE IN REPAIR.** Preparation of the furnace for the next charge. Furnace troubles. Repair materials. **SECTION 7: FACTORS AFFECTING ECONOMY OF FURNACE OPERATION.** Fuel consumption. Rate of steel production. **SECTION 8: THE CHEMISTRY OF BASIC OPEN-HEARTH MELTING.** Chemistry of the ore boil. Oxidation and neutralization of silicon and manganese. Behavior of sulphur during melting and the ore boil. Chemistry of the lime boil. Preliminary adjustments of the slag; objects of the run-off. Chemistry of the working period. Limitations of the various systems of control. Laws of chemical action. Composition of slags. Slag composition in relation to refining reactions. Chemistry of the finishing period. Relation of carbon to oxygen in the metal. Chemistry of steel in the ladle and molds. Nonmetallic inclusions. Refractory material. Oxygen and sulphur. **SECTION 9: OPERATION OF AN ACID OPEN-HEARTH FURNACE.** Materials for the charge. Proportion of scrap to pig iron. Grade of scrap and iron for the charge. Manner of charging. Melting. Adjusting conditions after melting. Working the heat. Finishing acid open-hearth steel. Tapping. Additions to the heat. Teeming. Preparation of the furnace for the next charge. **SECTION 10: CHEMISTRY OF THE ACID OPEN-HEARTH FURNACE.** Chemistry of melting. Purifying reactions. Elimination of carbon during the melting period. Chemistry of the boil. **Bibliography.**

CHAPTER 16

Electric Furnace Steelmaking. 334

SECTION 1: DEVELOPMENT AND PRESENT STATUS OF ELECTRIC MELTING FURNACES. Methods of electric heating. Historical development of electric melting furnaces. Direct-arc furnaces. Indirect-arc furnaces. The induction furnace. Electric reduction furnaces. Furnaces of special design. Field of application of electric-arc furnaces. General comparison of basic and acid electric-arc-furnace processes. Cold scrap vs. hot metal. Advantages of the electric-arc furnace. Disadvantages of the electric-arc furnace. **SECTION 2: DIRECT-ARC ELECTRIC FURNACES AND AUXILIARIES.** Mechanical parts. Capacity of furnaces. The furnace shell and lining. Charging methods. Top-charged furnaces. Door-charged furnaces. Auxiliary equipment. Pouring facilities. Ladle drying and preheating. Stopper drying. Hot-top drying. Electrodes. Soderberg electrodes. The power transformer. Tap changers. Reactors. Size of transformers. The secondary circuit. The primary power supply with circuit breaker. Control of power supply to the charge. Operator's control panel. Power requirements. **SECTION 3: THE BASIC ELECTRIC-ARC FURNACE PROCESS.** Stocking and charging facilities. Utilization of steel scrap. Scrap segregation. Methods of insuring proper segregation of scrap. Physical requirements of scrap. Selection of scrap charge. Charging the furnace. Melt-down and/or oxidizing period. Refining. Induction stirring. Tapping. Ladle practices. Mold practice. Pouring practice. Repairs to furnace bottom and banks. Electrode adjustments. Slag control in the basic process. **SECTION 4: THE ACID ELECTRIC-ARC FURNACE PROCESS.** Melting the charge. Working the heat. **SECTION 5: INDUCTION ELECTRIC FURNACE PROCESSES.** Melting the charge. Advantages of induction melting. Disadvantages of induction melting. **SECTION 6: VACUUM AND ATMOSPHERE MELTING. Bibliography.**

CHAPTER 17

Duplex and Triplex Steelmaking Processes. 359

SECTION 1: DUPLEX PROCESSES. Definition. Tilting open-hearth furnaces. Description of duplex plant. Continuous process maintaining a dominant pool. Preparing the furnace for charging. Cycle of operations. Advantages of the process. Deficiencies of the dominant pool method. The dry bottom or single heat duplex process. The charge. Working the heat. The slag. Combination scrap and blown metal method. Advantages and disadvantages of the duplex processes. **SECTION 2: TRIPLEX PROCESSES. Bibliography.**

CHAPTER 18

Castings—Steel and Iron. 366

SECTION 1: STEEL CASTINGS. Casting compared with other forms of shaping steel. Composition and mechanical properties of cast steels. Making steel for castings. Molding for casting steel. Patterns and molds. Making the mold. Machine

molding. Cored molds for hollow castings. Gates, risers and vents. **Steel casting and finishing operations.** Shaking out, cleaning, finishing and testing. **Heat treatment of steel castings.** Annealing. Normalizing. Quenching and tempering. Flame hardening. **Heat and corrosion-resistant steel castings.** Highly alloyed steels. Typical applications. Melting. Molding. Finishing operations. Methods of sampling and testing. **Precision steel castings.** **SECTION 2: IRON CASTINGS.** Pig iron for castings. **Iron composition vs. properties.** Forms of carbon in pig iron. Influence of silicon. Effects of manganese. Influence of sulphur. Influence of phosphorus. Effects of chromium. Influence of nickel. Influence of copper. Effects of molybdenum. Effects of titanium and aluminum. Influence of vanadium. Effects of special additives. **Iron-foundry melting methods.** The cupola. The air furnace. The electric furnace. **Kinds and uses of iron castings.** Chilled-iron castings. Malleable castings. Alloyed castings. Gray-iron castings. Nodular-iron castings. **Iron-foundry molding and casting practice.** Testing of cast iron. **Bibliography.**

CHAPTER 19

Plastic Deformation of Steel 385

SECTION 1: INTRODUCTORY. Objectives of mechanical treatment. Crystalline nature of steel. Elasticity and plasticity. Mechanism of plastic deformation. Strain hardening. Recovery. Recrystallization. Hot working and cold working defined. **SECTION 2: HOT WORKING AND ITS EFFECTS.** Finishing temperature. Fiber and banding. **Principal methods for hot working.** Hammering. Pressing. Extrusion. Mechanical forging. Upsetting. Hot rolling. Miscellaneous hot-working methods. Comparison of methods for hot working. **SECTION 3: COLD WORKING AND ITS EFFECTS.** Principal cold-working methods. Cold rolling. Cold drawing. Cold extrusion. **Bibliography.**

CHAPTER 20

Ingots and Their Preparation for Rolling 391

SECTION 1: INGOT CHARACTERISTICS. Ingots. Ingot characteristics. Nature of the cooling of an ingot. Time for solidification of ingots. **SECTION 2: TYPES OF INGOT STRUCTURES.** Pipe. Blowholes. Segregation. Columnar structure. Internal fissures. Ingot cracks. Nonmetallic inclusions. Scabs. Mold coatings. **SECTION 3: CONTROL OF INGOT STRUCTURE.** Steelmaking and deoxidation practices. Rimmed steels. Capped steel. Semi-killed steel. Killed steel. **SECTION 4: HEATING INGOTS FOR ROLLING.** Function of soaking pits. "Burning" of ingots. Overheating of killed and semi-killed non-hot-topped ingots.

CHAPTER 21

Construction and Operation of Heating Facilities 399

SECTION 1: PRINCIPLES OF FURNACE DESIGN. Objectives and general metallurgical requirements. Basic elements of furnaces. Furnace size and capacity. Furnace type and shape. Thermal efficiency. Materials of construction. **SECTION 2: SOAKING-PIT FURNACES.** Introductory. Types of soaking-pit furnaces. Auxiliary facilities. Ingot pit cranes. Ingot delivery facilities. Mill delivery facilities. Cinder removal facilities. Fuel, air and draft facilities. Objectives in modern soaking-pit design. Modern heating practices. Operating statistics. **SECTION 3: REHEATING FURNACES.** Furnace types. General considerations in furnace-type selection. Operating statistics. **SECTION 4: HEAT-TREATING FURNACES.** General design requirements. Method of heat application. Atmosphere control. Batch-type furnaces. Continuous furnaces.

CHAPTER 22

Construction and Operation of Rolling Mills 420

SECTION 1: TYPES OF MILLS. General classification. Arrangement of mills. Specialty mills. **SECTION 2: ROLLING MILL ACCESSORIES.** Lead spindle. Spindles. Bearings. Roller bearings. Chock bearings. Arrangement of the chocks. Housings. Screw-down mechanism. Edgers or edging rolls. Front and back roller tables. Manipulators. Guides and guards. Roll-changing devices.

CHAPTER 23

Rolling-Mill Roll Manufacture..... 431

SECTION 1: ROLLING-MILL ROLL DESIGN. Principal parts of rolls. Procedure in designing. Elements of good roll design. **SECTION 2: CASTING OF ROLLING-MILL ROLLS.** Steel-base rolls. Cast steel rolls. Built-up rolls. Forged-steel rolls. Iron-base rolls. Chill rolls. Grain-iron rolls. Composite or overflowed rolls. Ductile-iron rolls. **Bibliography.**

CHAPTER 24

Mill Drives and Power Requirements..... 441

SECTION 1: INTERRELATION BETWEEN ELECTRIC-POWER SUPPLY AND THE DEVELOPMENT OF MAIN MILL DRIVES. **SECTION 2: DEVELOPMENT OF MAIN MILL DRIVES.** **SECTION 3: POWER REQUIREMENTS IN THE STEEL INDUSTRY.** Power requirements for various operations in the production of steel. **SECTION 4: FACTORS WHICH AFFECT THE SIZE AND TYPE OF MAIN-DRIVE MOTORS.** **SECTION 5: TYPES OF MOTORS FOR MAIN DRIVES.** Synchronous motors. Squirrel-cage motors. Wound-rotor induction motors. Direct-current motors. **SECTION 6: FLYWHEELS—HOW THEY WORK AND WHERE THEY ARE USED.** Energy stored in a flywheel. Amount of energy available for regulation. Acceleration and retardation of the wheel. Induction-motor characteristics. Motor load curves. **SECTION 7: VARIOUS MEANS FOR OBTAINING ADJUSTABLE SPEEDS.** Control of two-speed AC motors. AC-motor speed control by secondary resistance. Variable speed controls for AC motors. Variable speed controls for DC motors. Ward-Leonard control. Relay and continuous-feedback systems. Rotating regulating systems. Magnetic-amplifier regulating system. Electronic control elements. **SECTION 8: REVERSING-MILL DRIVES.** General characteristics. The flywheel motor-generator set. **SECTION 9: THREE-HIGH MILL DRIVES.** **SECTION 10: CONTINUOUS-MILL DRIVES.** Wide hot-strip mills. Tandem cold-reduction mills. Continuous billet mills. Continuous bar mills. Continuous rod mills. Continuous seamless-tube mill. **SECTION 11: MOTOR-ROOM VENTILATION.** **SECTION 12: AUXILIARY DRIVES.** Table rollers. Screw-downs. Manipulators and side guards. Blooming-mill shears. **SECTION 13: FUTURE DRIVES.** **Bibliography.**

CHAPTER 25

Rolling of Steel Ingots to Blooms, Slabs and Billets..... 463

SECTION 1: PRODUCTION OF BLOOMS AND SLABS. Introductory. General features of blooming and slabbing mills. Primary-mill activities. Two-high reversing mill. Two-high tandem mill. Three-high mill. Operating units comprising a blooming mill. Rolling. Shearing. Combinations of conventional-type mills for special purposes. Two two-high reversing mills in tandem. Tandem and three-high mill in tandem. Four-stand and five-stand tandem mills in tandem. Design of blooming-slabbing mill roll stands. Foundations. Stand design. Roll design and rolling procedures. Roll design. Effect of pass design on rolling procedures. Convexity of passes. Depth of passes. Bearings. Roll-opening indicators. Roll-changing devices. Cooling water. Manipulators. **SECTION 2: PRODUCTION OF BILLETS.** Development of the billet mill. Types of billet mills. Three-high billet mills. Cross-country billet mills. Advantages of cross-country mills. Continuous billet mills. Six-stand continuous mill at Lorain Works. Four-stand continuous mill at Lorain. Hot-scarfing machines. Roll adjustment. Shears. Identification of billets. **Bibliography.**

CHAPTER 26

Preparation of Semi-finished Steel for Finishing..... 493

SECTION 1: SURFACE DEFECTS ON SEMI-FINISHED STEEL. Ingot cracks. Scabs. Scams. Cinder patch. Burned steel. Laps. **SECTION 2: INSPECTION.** Bases for inspection. Pickling for inspection. **SECTION 3: REMOVAL OF DEFECTS.** Hand chipping. Machine chipping. Scarfing. Hand scarfing of cold steel. Mechanical scarfing of hot steel. Grinding. Material handling. **SECTION 4: CONTROLLED COOLING OF SEMI-FINISHED PRODUCTS.** Purposes. Nature and prevention of flakes. Development of controlled-cooling practices. **Bibliography.**

CHAPTER 27

Rolling of Carbon-Steel Plates..... 503

SECTION 1: PLATE-MILL OPERATIONS AND PRODUCTS. Mill operations. Heating. Descaling methods and equipment. **SECTION 2: GENERAL TYPES AND OPERATING CHARACTERISTICS OF PLATE MILLS.** Two-high pull-over mills. Two-high single-stand reversing mills. Three-high mills. Four-high reversing mills. Tandem mills. Semi-continuous and continuous mills. Universal mills. Plate-rolling variables. Leveling. Cooling. Shearing. Identification, inspection, and loading. **SECTION 3: DESCRIPTIONS OF TYPICAL EXISTING PLATE MILLS.** Three-high plate mill. The 160-inch mill at Gary Works. Four-high reversing plate mill. Homestead District Works 160-inch four-high mill. Semi-continuous plate mill. The 100-inch semi-continuous plate mill at Homestead District Works. Continuous plate mill. The 96-inch four-high continuous plate mill at South Works. Universal plate mill. The 30-inch universal plate mill at South Works.

CHAPTER 28

Railroad Rails and Joint Bars..... 523

SECTION 1: ROLLING OF RAILROAD RAILS. Historical development of rail sections. Mills for rolling rails. Methods of rolling. Designing the rolls for rails. Stages of reduction. The section. Roll preparation. Rolling practice. Standard rails. Girder rails. Crane rails. Light rails. Finishing operations for standard rails. Cutting and cambering. Marking and branding. Controlled cooling. Testing of standard rails. Finishing operations. End hardening. Finishing and inspection of crane rails. Finishing and inspection of girder and light rails. **SECTION 2: THE ROLLING OF RAIL-JOINT BARS.** Types of rail joints. Present rail joints. Problems in rolling rail-joint bars. Finishing joint bars. Cold-worked joint bars. Hot-worked joint bars. Hot-worked and oil-quenched joint bars. Welded rail joints.

CHAPTER 29

Structural and Other Shapes..... 532

SECTION 1: EQUIPMENT FOR PRODUCING SHAPES. **SECTION 2: ROLLING METHODS AND PROCEDURES.** **SECTION 3: FINISHING AND INSPECTION.** Bibliography.

CHAPTER 30

Merchant-Bar Production 540

SECTION 1: MILLS AND THEIR PRODUCTS. Evolution of the bar mill. Mills for rolling light, narrow and flat material. Rail-slitting mills. Roll design for bar mills. **SECTION 2: FINISHING AND SHIPPING MERCHANT-MILL BAR PRODUCTS.** Coordination of finishing and shipping functions. Bar finishing procedures and equipment. Relation of mill delivery equipment to subsequent finishing operations. Methods of cutting product to length. Machine straightening. Sizing, turning and centerless grinding. Processing bar coils. Pickling. Stationary or vat pickling. Temperature of the pickling bath. Inhibitors. Common pickling difficulties. Grit blasting. Bar inspection and testing. Conditioning methods and equipment. Narrow flat-rolled products. Band, hoop and cotton tie. Concrete reinforcing bar. Packaging and loading. Material-handling equipment. **SECTION 3: HEAT TREATING CARBON AND ALLOY BAR STOCK.** Processes and their effects. Annealing. Full annealing. Isothermal annealing. Process or subcritical annealing. Spheroidization. Normalizing. Quenching and tempering. Heat-treating plants. Furnaces. Control of temperature. Methods of loading. Auxiliary equipment. Bibliography.

CHAPTER 31

Production of Wrought-Steel Wheels..... 568

Introduction. Parts and classification of wrought-steel wheels. Classes of wrought-steel wheels. Outline of methods for forming solid wrought-steel wheels. Preparation of blocks. Forging of wheel blanks. Heating the blocks for forging. First forging of the block. Second forging. Punching the hub bore. Rolling operations on wheels. Reheating the blanks for rolling. The rolling mill. The rolling process. Effect of rolling. Finishing wrought-steel wheels. Stamping. Punching

THE MAKING, SHAPING AND TREATING OF STEEL

web holes. Coning. Controlled cooling. Inspection of wheels. Machining and final inspection. Heat treatments for wrought-steel wheels. Bibliography.

CHAPTER 32

Production of Railroad Axles..... 578

General. The axle works. Methods of forming axles. Inspection of the blooms. Heating the blooms. The forging operation. Finishing processes for axles. Straightening. Cutting-off and centering. Rough turning. Boring. Axle heat-treating plant. Heat-treating furnaces. Advantages of heat-treating axles. Testing equipment. Bibliography.

CHAPTER 33

The Manufacture of Hot-Strip Mill Products..... 583

SECTION 1: HISTORICAL DEVELOPMENT. SECTION 2: CLASSIFICATION OF FLAT-ROLLED STEEL PRODUCTS. Flat hot-rolled finished products classified. Flat cold-rolled products classified. **SECTION 3: SOURCES AND TYPES OF STEEL FOR SHEETS, STRIP AND TIN PLATE.** Chemical compositions. Steelmaking processes. Slabs. **SECTION 4: CONTINUOUS HOT-STRIP MILLS.** Development and output. General arrangement of modern mills. Control of finished product quality. A modern wide continuous mill. Product disposition. Metallurgy of hot strip. **SECTION 5: HAND HOT MILLS.** Development. Process. Equipment and operation. **SECTION 6: OXIDE REMOVAL (PICKLING AND SHOT BLASTING).** Necessity for removal. Type of oxide. Pickling. Process description. Inhibitors. Wetting agents. Continuous pickling lines. Batch pickling. Shot blasting. Bibliography.

CHAPTER 34

Manufacture of Cold-Reduced Flat-Rolled Products..... 602

SECTION 1: PRINCIPLES OF COLD REDUCTION. Introduction. Sequence of operations in cold reduction. **SECTION 2: ROLL ARRANGEMENT FOR COLD REDUCTION. SECTION 3: TYPICAL MILL LAYOUTS.** Four-high tandem mills. Four-high reversing mills. Two-high cold mills. **SECTION 4: DISPOSITION OF PRODUCT. SECTION 5: COLD-REDUCED STRIP CLEANING. SECTION 6: HEAT TREATMENT OF COLD-REDUCED STEEL.** Purposes and types of heat treatment. **SECTION 7: EFFECTS OF HEAT TREATMENTS ON MICRO-STRUCTURE.** Box annealing. Normalizing. Continuous annealing. Bibliography.

CHAPTER 35

Theory of Corrosion..... 615

SECTION 1: CAUSES OF CORROSION. The mechanism of corrosion. Factors which affect corrosion rate. Moisture. Salts. Acids. Alkalis. Oxygen and oxidizing compounds. Sulphur compounds. High temperatures. Galvanic action. Stray currents. Concentration cells. Stress. Abrasion, erosion and cavitation. Other surface effects. Metallurgical factors. **SECTION 2: METHODS OF PREVENTING CORROSION.** Material selection. Appropriate design. Protective coatings. Treatment of environment. Cathodic protection. Periodic cleaning. Bibliography.

CHAPTER 36

Protective Coatings for Steel..... 620

SECTION 1: PURPOSE OF PROTECTIVE COATINGS. Functional coatings. Coatings combining decorative and protective properties. **SECTION 2: PREPARATION OF STEEL FOR APPLICATION OF COATINGS.** Importance of clean surface. Pickling. Shot or sandblasting. Alkaline cleaning. Solvent degreasing. **SECTION 3: METALLIC PROTECTIVE COATINGS.** Methods of applying metallic coatings. Hot-dip processes. Metal spraying. Metal cementation. Metal cladding. Fusion welding of coatings. Electroplating. Miscellaneous metallic coatings. **SECTION 4: SURFACE CONVERSION COATING. SECTION 5: CHEMICAL TREATMENT OF STEEL SURFACES. SECTION 6: CHEMICAL TREATMENT OF METALLIC COATINGS. SECTION 7: VITREOUS-ENAMEL COATINGS. SECTION 8: MISCELLANEOUS INORGANIC COATINGS. SECTION 9: ORGANIC COATINGS. Bibliography.**

CHAPTER 37

The Manufacture of Tin Plate. 630

SECTION 1: PRODUCT TERMINOLOGY. Black plate. Tin plate. Hot-dipped tin plate. Electrolytic tin plate. Symbols and definition of base box. **SECTION 2: OCCURRENCE, MINING AND REFINING OF TIN.** Occurrence. Mining. Refining. Properties and uses of tin. **SECTION 3: USES AND IMPORTANCE OF TIN PLATE.** **SECTION 4: PROCESSING OF STEEL FOR TIN PLATE.** Types of steel used. Equipment and practice. **SECTION 5: HOT-DIPPED TIN PLATE.** Shearing practice. White-pickling practice. Electrolytic pickling. The hot-tip tinning operation. Coke tin plate. Tinning-roll practice. **Hot-dipped tin plate coating weights.** Coke tin plate. Charcoal tin plate. Silver tin. Sampling. Heavy-gage tin plate. Manufacture of charcoal tin plate. Assorting of hot-dipped tin plate. **SECTION 6: ELECTROLYTIC TIN PLATE.** Introduction. Basic principles of electroplating. Commercial electrolytic tinning equipment. **SECTION 7: METALLURGICAL ASPECTS.** General. The steel base. The tin-iron alloy layer. The tin layer. The tin-oxide layer. The oil film. Application of oil films to electrolytic tin plate. **SECTION 8: CORROSION RESISTANCE.** Atmospheric corrosion. Discoloration of the interior of cans. Hydrogen-producing corrosion. Characteristics of tin plate affecting its corrosion. Characteristics of the steel base affecting the corrosion of tin plate. Effect of tin coating thickness on corrosion of tin plate. Lacquered tin plate. **Bibliography.**

CHAPTER 38

Long Terne Sheets and Terne Plate. 655

Long terne sheets. Long terne coatings. Composition and preparation of steel base. Long terne coating application. Inspection and testing of long terne sheets. Continuous strip production of long ternes. Applications for long terne sheets. Terne plate. **Bibliography.**

CHAPTER 39

Production of Galvanized Sheet and Strip. 660

SECTION 1: GENERAL. Production and uses of galvanized sheet and strip. Factors influencing effectiveness of galvanized coatings. Coating weight and gage requirements. General quality designation. Specialty products. **SECTION 2: METALLURGICAL FEATURES OF THE HOT-DIP GALVANIZING PROCESSES.** Processes employed. Characteristics of hot-dipped coatings. Coating metal used in hot-dip galvanizing. Steels used for hot-dip galvanizing. Mill treatment of steel prior to galvanizing. Special finishes. **SECTION 3: HOT-DIP SHEET GALVANIZING.** Pickling for sheet galvanizing. Equipment for sheet galvanizing. General arrangement and operation of a sheet-galvanizing line. **SECTION 4: CONTINUOUS (STRIP) HOT-DIP GALVANIZING.** General arrangement and operation of continuous galvanizing lines. **SECTION 5: TESTING GALVANIZED SHEETS.** Weight of coating determination. Bend tests. Beading tests. Lockseam test. Tensile properties determination. Hardness tests. Ductility test. Ferritic grain-size determination. **Bibliography.**

CHAPTER 40

The Manufacture of Steel Wire and Steel Wire Products. 674

SECTION 1: HISTORY AND IMPORTANCE OF STEEL WIRE. Historical. Present importance of steel wire industry. Principal uses of steel wire. Early method of manufacture. **SECTION 2: CLASSIFICATION OF STEEL WIRE.** Bases for classification. Kinds and composition of steel used for wire. Wire shapes. Sizes of wire. Classification of common round wire according to size. Surface finishes of wire. Temper of wire. **SECTION 3: ROLLING THE WIRE ROD.** The wire rod. Types of rod mills. The continuous rod mill. The Morgan mill. Modern continuous rod mills. Layouts for rolling small billets. The looping continuous rod mill. Layouts for rolling 4-inch by 4-inch billets. Operation of continuous rod mills. The Garrett rod mill. Accessories to Garrett's mill. Number of strands. Floors. Layouts of Garrett mills. Combination mills. The double Belgian mill. Continuous and looping mills compared. Rolls for rod mills. Designing the passes. Housings and guides. Rod reels. Defects in rods. **SECTION 4: OUTLINE OF THE WIRE-DRAWING PROCESS.** Preparing the rod for drawing. Drawing the rod. Draft, drawing and process wire. Dry drawing and wet drawing. Types of wire. **SECTION 5: PROCESSES AND EQUIPMENT FOR PREPARING RODS AND WIRE**

FOR DRAWING. Importance of cleaning. Method of cleaning. Manner of handling the material. Types of cranes. Construction of tanks. Arrangement of tanks. Concentration of acid. Temperature for cleaning. Inhibitors. Time of cleaning. Rinsing. Coatings. Process for lime coating. Coatings for dry drawing. Baking. **SECTION 6: WIRE-DRAWING EQUIPMENT.** Dies. Die holes. Diamond dies. The block. Drawing machines. Drawbench. Bull blocks. Motor blocks. Continuous machines. Intermediate machines. Fine-wire machines. Drawing frames. **Auxiliary equipment.** Pay-off reels. Welders. Safety stop. Pointers. "Turks-head" shaped-wire drawing machine. Heating effect in wire drawing. **SECTION 7: WIRE-DRAWING PROCESSES AND OPERATIONS.** Results of cold drawing. Effect of drawing upon mechanical properties. The cause of these changes. Limitations of drawing. **Dry drawing.** Dry drawing low-carbon coarse wires. Drawing single-draft coarse wires. Drawing two-, three-, and four-draft wires. Drawing five- and six-draft wire. Drawing No. 14, 15 and 16 wires. Drawing high-carbon, or special wires. **Wet drawing.** Manner of handling material for wet drawing. Number and sequence of operations for fine-wire drawing. Drawing copper wire. Precautions in drawing—proper alignment of the die. Drawing limits and tolerances. **Special finishing operations.** Straightening and cutting wire. Whirls. Roll straighteners. Stretching machines. **Inspection and testing.** Importance of inspection. Final tests on wires. Defects in wire. Size and shape. Internal defects. Surface defects. Mechanical properties. **SECTION 8: HEAT TREATMENT OF WIRE.** Heat-treating processes. Importance and purposes of annealing. Normalizing (cycle annealing). Annealing for definite structures. Process annealing to soften hard-drawn wires. Process annealing. Size of grains. The conditions for process annealing. Time and temperature for annealing. **Methods of annealing wire.** Muffle annealing. Salt-bath annealing. Pot annealing. Equipment for pot annealing. Advantages of pot annealing. Continuous lead annealing. Advantages of lead annealing. Principal use of lead annealing. **Patenting.** Methods of patenting. Properties of patented wires. **Hardening and tempering.** Methods of hardening and tempering wire. **Austempering.** **SECTION 9: PROTECTIVE METALLIC COATINGS.** Kinds of coatings. **Wire galvanizing.** Advantages of galvanizing. Processes preliminary to hot galvanizing. Apparatus for hot galvanizing. Wiping the wire. Cooling the coated wire. Coiling the wire. Some features of the operations for hot galvanizing. Quality of the zinc coat. Structure of the zinc coat. **Electro galvanizing.** Equipment for electro galvanizing. Operation of the process. Factors in controlling the thickness of the coat. Tests for galvanized coatings. Methods of carrying out the copper sulphate test. Principles of the test. Value of the copper sulphate test. **Wire tinning.** Aluminum coatings. **SECTION 10: TYPICAL FINISHED WIRES FOR MANUFACTURING PURPOSES.** Common wires. Bright Bessemer wire. Bright basic wire or bright hard basic wire. Bright soft basic wire. Medium classifications. Annealed wires. Cold-heading wire. Liquor-finished fine and weaving wire. Welding wire. Scratch brush wire. Market wire. Uses of common wire. **High-carbon or special wires.** Rope wire. Music wire. Piano wire. Tinned and liquor-finish P.S.R. tire wire. Spoke wire. Valve spring wire. Tempered wire. Tinned armature-binding wire. Metal-stitching wire. Other special wires. **Stainless steel wire.** Stainless cold-rolled strip steel. Cold-rolled carbon steel strip. Flat wire. **SECTION 11: SOME FABRICATED STEEL-WIRE PRODUCTS.** Importance of fabricated wire products. **Wire nails.** Nail machines. The head. Feeding. Pinching. Cutting. Expelling. Finishing common nails. **Wire fence.** Woven-wire fence. Barbed-wire fence. **Concrete reinforcement.** Prestressed concrete. **Bale ties.** **Wire rope.** Fabrication of wire rope. Stranding. Laying or closing. Types of wire ropes. **Wire springs.** Compression springs. Extension springs. Helical springs. Torsion springs. Upholstery springs. Clock and motor flat springs. Jig springs and specially formed wires. **Spring terms.** Bluing. Tested springs. Scale testing. Pitch. Active and inactive coils. Initial tension. **Bridge wire.** **Bibliography.**

CHAPTER 41

Manufacture of Steel Tubular Products. 724

SECTION 1: HISTORY AND CLASSIFICATION OF STEEL TUBULAR PRODUCTS. Events leading to development of the butt-weld process. First seamless tubes. Innovations by Briggs and Riverside Iron. The present importance of the steel tubular industry. Classification of steel tubular products. Modern methods of manufacturing welded tubular products. Seamless tubular products. Pipe. Varieties of pipe. Sizes of pipe. **SECTION 2: BUTT-WELDED PIPE.** Conventional butt-weld process. Rolling the skelp. Example of a skelp mill. Operation of the mill. Shearing the skelp. The butt-welding furnace. The welding machine. Operation of the butt-welding furnace. The hot finishing of pipe. The sizing rolls. The stretch-reducing mill. Straightening rolls. **Continuous butt-weld process.** Production of skelp. Uncoiling the skelp. Welding unit for joining ends of coils.

"Looping" the skelp. Furnace "threading." The butt-welding furnace. **Forming**, welding and reducing mills. Hot sawing and preliminary cooling. Sizing, cooling and inspecting. **SECTION 3: ELECTRIC-RESISTANCE-WELDED TUBING.** Steps in manufacture. Slitting. Forming. Welding the tube. Sizing the welded tube. Finishing. **SECTION 4: ELECTRIC-WELDED LARGE DIAMETER PIPE.** Applications of the process. Steps in manufacture. Shearing and planing. Crimping. Bending. Welding. Sizing or expanding. Finishing. **SECTION 5: SEAMLESS STEEL TUBULAR PRODUCTS.** Historical. Scope and requirements of seamless tube products. Steelmaking practices. Rolling mills. Sequence of operations. The Mannesmann machine. The operation of piercing. The action of the rolls. The principle involved in forming the cavity. Flow of the metal in piercing. Double piercing. Rotary rolling. The plug rolling mill. The operation of plug rolling. The reeling machine. Sizing the tube. Warm working. Spray-quenched deep well casing. Cold-expanded seamless pipe. The continuous seamless process. Rolling heavy-wall tubing. Seamless fabricating practices. **SECTION 6: COLD-DRAWN OR COLD-FINISHED TUBES.** Principle of cold drawing. The draw bench. Preliminaries to cold drawing. The cold-drawing operations. The tube reducing or Rockrite process. Principle of Rockrite process. The Rockrite machine. Preliminaries to Rockriting. Rockrite machine operation. Annealing and redrawing. Finishing operations on cold-drawn annealed tubes. Mechanical tubing. Pressure tubing. Dimensional tolerances of cold-drawn mechanical tubing. Surface finishes. Hot finished. Normalized. Soft annealed. Medium annealed. Finish annealed. Hard drawn (unannealed). Ellwood B.F. (Bright Finish). Bright annealed. Specially smooth (cylinder finish). Pickled finish. Sandblasted finish. Polished finishes. Annealing of plain low-carbon steel tubing. Hot-finished tubing. Finish anneal. Soft annealing. Cold-drawn tubing. Medium anneal. Normalizing. **SECTION 7: THE CUPPING PROCESS.** Applications of the process. Chief details of the cupping process. Hot drawing the cupped piece. Forming cylinders. Spinning. **SECTION 8: HOT EXTRUSION.** Historical. Advantages of hot extrusion. The extrusion press. The extrusion operations. Piercing billets. Operation of the press. Tooling. Power supply. Finishing operations. **SECTION 9: FINISHING OPERATIONS.** Straightening. Inspection and cutting. Pipe joints. Joints with threads and couplings. Threading pipe. Chip space. Clearance. Lead or throat. Number of chasers. Dies. Lubricant. Gaging pipe threads. Coupling forgings. Finishing steel couplings. Testing the pipe. Oiling. Types and uses of joints. Upsetting. Internal upset casing with long couplings. Seamless buttress-thread casing (nonupset). A.P.I. casing with long coupling. A.P.I. standard casing. A.P.I. line pipe. A.P.I. external upset tubing. A.P.I. standard tubing. A.P.I. internal upset drill pipe. Standard pipe. Flanged joints. Threaded flange joint. Vanstone type flanged joint. Expanded end for welding and double expanded ends for welding Dresser-type joints. Victaulic joint. Galvanizing. Value of zinc coating for pipe. **Bibliography.**

CHAPTER 42

Principles of Heat Treatment of Steel. 788

SECTION 1: METALLOGRAPHY. The importance of heat treatment. The science of heat treatment. The constituents of steel. Ferrite. Cementite. Austenite. Pearlite. The iron-carbon equilibrium diagram. Ledeburite. Graphite. The iron-iron carbide equilibrium diagram for steels. Critical temperatures. Changes occurring on heating and cooling pure iron. Changes occurring on heating and cooling hypoeutectoid steels. Changes occurring on heating and cooling eutectoid steels. Changes occurring on heating and cooling hypereutectoid steels. The A_1 formerly designated critical temperature. The effect of alloys on the equilibrium diagram. Grain size. Grain size and properties. Determination of grain size. Fine- and coarse-grain steels. The transformation of austenite. Isothermal transformation diagrams. Transformation to pearlite. Transformation to bainite. Transformation to martensite. **Microstructure and mechanical properties.** Properties of pearlite. Properties of bainite. Properties of martensite. Properties of tempered martensite. **Factors affecting transformation rates.** Effect of carbon content. Effects of alloys. Effect of grain size. **Transformation on continuous cooling.** **SECTION 2: HARDENABILITY.** Relationship of hardenability to transformation rates. How hardenability is expressed and measured. Hardenability and heat treatment. **SECTION 3: HEAT-TREATMENT PROCEDURES.** Quenching and tempering. Heating. Quenching. Tempering. Martempering. Austempering. Normalizing. Annealing. Full anneal. Isothermal annealing. Spheroidize annealing. Process annealing. **SECTION 4: CARBURIZING.** Pack carburizing. Gas carburizing. Liquid carburizing. Heat treatment of carburized parts. Nitriding. **Bibliography.**

CHAPTER 43

Carbon Steels 816

SECTION 1: CLASSIFICATION AND APPLICATION. SECTION 2: FACTORS AFFECTING CARBON-STEEL PROPERTIES. Carbon content and properties. Effect of microstructure and grain size. **SECTION 3: FACTORS AFFECTING MICROSTRUCTURE AND GRAIN SIZE.** Composition. Microstructure of cast steels. Effects of hot working. Effects of cold working. **SECTION 4: HEAT TREATMENT OF CARBON STEELS.** Annealing. Normalizing. Quenching and tempering. Austempering. **SECTION 5: AGING IN CARBON STEELS. SECTION 6: EFFECT OF RESIDUAL ELEMENTS. Bibliography.**

CHAPTER 44

Alloy Steels 826

SECTION 1: FUNCTIONS OF THE ALLOYING ELEMENTS. Hardenability. Effects of the alloying elements on hardenability. The multiplying factor principle. Effects of the alloys on tempering. **Other functions of the alloying elements.** Ferrite strengthening. Corrosion resistance. Abrasion resistance. Magnetic (electrical) characteristics. **SECTION 2: THE AISI ALLOY STEELS.** Classification and standardization. Applications of the AISI alloy steels. Hardenabilities of the AISI alloy steels. **SECTION 3: ALLOY TOOL STEELS.** Compositions and applications. Heat treatment. General. High-speed steel. **Bibliography.**

CHAPTER 45

High-Strength Low-Alloy Steels 841

Engineering function of the high-strength steels. Historical background. Corrosion and welding. Definition. Fundamental characteristics. Corrosion resistance. Formability. Weldability. Notch toughness. Fatigue resistance. Abrasion resistance. Compositions, properties and characteristics and applications. **Effect of chemical composition on properties and characteristics.** Carbon. Manganese. Phosphorus. Copper. Other elements. Applications. **Bibliography.**

CHAPTER 46

Silicon-Steel Electrical Sheets 848

Introductory. Classification and uses of electrical sheets. Low-silicon steels. Intermediate silicon steels. High-silicon steels. **Processing of electrical sheets.** Grain-oriented. Nonoriented. Core plating. **Factors affecting magnetic properties.** Composition. Grain orientation. **Effects of silicon on iron-carbon alloys. Mechanical properties. Definitions of terms and methods of testing.** Magnetic aging. Core loss. Eddy-current loss. Hysteresis. Permeability. Magnetic flux density or induction. Magnetomotive force. Magnetizing force. Saturation. Interlamination resistance. Lamination factor or space factor. **Bibliography.**

CHAPTER 47

Stainless Steels 854

General. Constitution. Iron-chromium system. Iron-chromium-nickel system. Iron-chromium-carbon system. **Manufacture and fabrication.** Melting. Hot working. Cold working. Rolling ingots to blooms and slabs. Rolling of billets. Rolling of plates. Rolling of bars. Rolling of sheet and strip. **Heat treatment.** Heat treatment of the iron-chromium stainless steels. Iron-chromium-nickel stainless steels. **Corrosion resistance.** Atmospheric corrosion. Elevated-temperature corrosion. Intergranular corrosion. Pitting corrosion. **Mechanical properties.** Low-temperature properties. Room-temperature properties. Elevated-temperature properties. **Applications.** Martensitic grades. Ferritic grades. Austenitic grades. Summary. **Bibliography.**

CHAPTER 48

Steels for Elevated-Temperature Service 872

SECTION 1: CLASSES OF STEEL. SECTION 2: FACTORS AFFECTING HIGH-TEMPERATURE PROPERTIES. Composition and temperature. Heat treatment

(microstructure). Grain size. Cold working. Manufacturing practice. **SECTION 3: BEHAVIOR OF STEELS AT ELEVATED TEMPERATURE.** Internal stability. Carbide instability. Aging. Temper brittleness. Embrittlement of ferritic chromium steels. External or surface stability. Scaling and corrosion resistance. Effect of various atmospheres. Caustic embrittlement of boiler plates. Thermal conductivity. Thermal expansion. Modulus of elasticity. **Bibliography.**

CHAPTER 49

Mechanical Testing 881

SECTION 1: INTRODUCTION. SECTION 2: THE TENSION TEST. Testing machines. Extensometers. Specimens. The tension test and properties which are determined. Stress. Strain. **Strength properties.** Modulus of elasticity (Young's modulus). Elastic limit. Proportional limit. Yield strength. Yield point. Tensile strength. **Ductility properties.** Elongation. Reduction of area. **Significance of the tension test. SECTION 3: HARDNESS TESTING.** The Brinell hardness test. The Rockwell hardness test. Rockwell superficial hardness tests. The Vickers or diamond pyramid hardness test. Miscellaneous hardness tests. The Shore scleroscope test. The Penatroscope. File hardness. The Monotron hardness test. The cloudburst tester. The Telebrineller (or Brinell meter). Microhardness tests. **Hardness conversion tables.** Significance and general utility of hardness tests. **SECTION 4: NOTCHED-BAR IMPACT TESTS.** Impact-testing methods. Significance and interpretation of notched-bar impact test results. **SECTION 5: FATIGUE TESTING.** Types of fatigue tests. Fatigue-testing specimen preparation. Presentation of fatigue-test data. Significance of laboratory small-scale fatigue tests. **SECTION 6: HIGH-TEMPERATURE TENSION, CREEP, RUPTURE AND HARDNESS TESTING.** The high-temperature tension test. The creep test. The rupture test. The high-temperature hardness test. **SECTION 7: USE OF HIGH-TEMPERATURE DATA IN DESIGN. SECTION 8: MISCELLANEOUS MECHANICAL TESTS.** Compression testing. Bend testing. Cupping tests. Strain-sensitivity and strain-aging sensitivity tests. Torsion testing. Shear testing. Wear testing. Damping capacity tests. **SECTION 9: NONDESTRUCTIVE TESTS.** Radiography. Magnetic methods. Ultrasonic methods. **Bibliography.**

CHAPTER 50

Gage Numbers 928

Origin of gages. Relation of gage number to thickness. British gages. United States sheet gages. Density of iron and steel. The tin plate gage. U. S. wire gages.

**THE MAKING, SHAPING
AND
TREATING OF STEEL**

Chapter 1

IRON IN ANTIQUITY

Prehistoric and Ancient Use of Iron—The antiquity of man's use of iron is attested by references to that metal both in fragmentary writings and in inscriptions on monuments, palaces and tombs that survived the collapse of such ancient civilizations as those of Assyria, Babylonia, Egypt, China, India, Greece and Rome. In addition to these written records, archeologists have unearthed actual iron tools, weapons and ornaments used by many of these historic ancient peoples, as well as some implements and jewelry of iron in sites in many parts of the world that were occupied by prehistoric peoples who left no written records. The chemical composition and the properties of the metals in these specimens vary widely. Some closely resemble modern wrought iron; some are more nearly like steel as it is known today. For the sake of simplicity, all of the ancient ferrous metals discussed in this chapter will be referred to as "iron." In later chapters the modern meanings of "iron," "steel," "wrought iron," etc., will be clearly defined and the words used in their proper, more exact sense.

Meteoric Iron—Mere mention of the use of iron in the oral traditions or writings of primitive or prehistoric peoples does not necessarily mean that they knew how to produce iron by extracting it from ore. Actually, there is evidence that most of the iron used in earliest times was not man-made, but was obtained from fragments of meteorites. This belief in the origin of the iron used by very ancient peoples is based on three facts. In the first place, practically all of their names for iron, when translated, mean "stone (or hard substance or metal) from heaven," "star metal" or have similar meanings that suggest that the metal they used came from outside the earth. Secondly, chemical analysis of numerous archeological specimens has established that they contain considerable quantities of nickel which likewise is found in similar quantities (usually 7 to 15 per cent, but as high as 30 per cent) in the iron of meteorites. The third instance supporting this belief is that many primitive peoples of relatively recent times used iron from meteorites to make useful implements. In several historical cases, the main masses of huge meteorites from which the natives had laboriously severed bits of the metal were still in existence in the places where they had fallen and still served as sources of supply.

Telluric (Native) Iron—Gold, silver, copper and some other metals known to the ancients often are found on or near the surface of the ground in a fairly pure metallic condition, in the form of nuggets or rough masses. Being bright in appearance, such native metals would be noticed readily and, as they are capable of being shaped by hammering without heating, they would be put to eventual use by primitive peoples. The softness of gold and silver makes them useless for ordinary tools and weapons, and their ultimate chief use would be for vessels and ornament. The metal copper, however, can be hardened appreciably by hammering it

without previous heating, and the very hammering required to shape a tool from native copper might make it sufficiently hard to be useful for many purposes.

Iron, however, is very rarely found in the native state. One of the few known occurrences of native iron is in Northwestern Greenland; the iron occurs as grains or nodules in basalt (an iron-bearing igneous rock) that erupted through beds of coal. Mention might be made of two very rare natural nickel-iron alloys, given the mineralogical names of awaruite (FeNi_2) and josephinite (Fe_2Ni_3), that have been found in the form of granules and small bean-shaped pebbles. It is improbable, therefore, that primitive man could have found any useful quantity of naturally occurring metallic iron, certainly not enough to account for the widespread distribution of iron artifacts that have been discovered by archeologists.

Man-Made Iron—From the foregoing it may be deduced that iron must have been a rare metal for many centuries and that any specimens of it would be highly prized by the possessor. It was not until man learned how to extract iron from its ores at will that it could have become a common metal.

Archeological evidence seems to indicate that a knowledge of how to obtain copper from its ores existed long before iron was intentionally made by man. Mixtures (alloys) of copper and tin that formed bronze, and of copper and zinc that formed brass, provided the ancients with metals that found widespread usage. In a book such as this, devoted to a discussion of iron and steel, space limitations permit only brief mention of these non-ferrous metals. It should be remembered, however, that for many years after man learned how to extract iron from its ores, the product probably was so relatively soft and unpredictable, and undoubtedly hard to work, that bronze in particular continued to be preferred for many tools and weapons. Eventually, iron supplanted the non-ferrous metals for these purposes when men learned how to master the difficult arts of smelting, forging and hardening iron.

The origin of the methods used by early man for extracting iron from its ores is unknown. The rocky, granular or earthy ores gave little promise or outward indication of their valuable content. Some have suggested that men learned the method accidentally when they built fires by chance on crude hearths built of iron-bearing rock, especially if the fire was in a location where a strong, natural draft caused it to burn fiercely. This is a possibility, since what could happen under such circumstances would meet the conditions now known to be required for extracting iron from its ores. These conditions are that the iron-bearing ore should be heated strongly in contact with hot carbon out of contact with air. Small lumps of ore on a hearth, surrounded completely by hot coals, might meet these requirements. The important iron ores consist mostly of combinations of iron with oxygen. The process just

outlined causes the oxygen of the iron oxide to combine with the hot carbon, leaving metallic iron; in modern language, the iron is said to have been reduced from its oxides, and the process whereby the reduction is effected is called **smelting**. Some of the early smelting processes are described in Chapter 11 of this book.

It may be assumed that such chance production of iron occurred often enough in the experience of one individual or tribe to attract attention and eventually to excite a desire to reproduce the process at will. It should be remembered, however, that the high melting point of iron kept it from ever becoming fluid under such conditions. Copper, on the other hand, could be obtained in the fluid state from the smelting operation, and was quite obviously a desirable product that could be shaped either by casting directly into molds or by hammering a solidified lump. Bronze and brass also could be melted in the furnaces available to the ancient metallurgist. The iron reduced in smelting, however, would collect in a loosely coherent mass or "sponge" of metallic granules that would contain much slag in its pores. There would be nothing in its appearance to indicate the potential value of the crude, sponge-like mass. The key step probably occurred when some early man first discovered that if this unattractive mass was hammered while still hot, slag would be forced out and a lump of reasonably sound metal would result. Repeated heating and hammering would eventually be found to further improve the product, since such operations were necessary to the shaping of the lump into a useful implement.

The manufacture of iron on a relatively large scale could be undertaken once the smelting process was established and its limitations, as outlined above, were understood. Some ancient peoples mastered the principles and practices of smelting iron much earlier than others, and many instances in history point to the rapid rise and eventual ascendancy of the iron-producing nations over their backward neighbors. It is not known definitely whether the knowledge of ironmaking spread from a single point of original discovery or whether it was developed independently in several widely separated localities.

Archeological Evidence—Some of the oldest known iron objects found in various localities include one piece found in the Great Pyramid (built about 2900 B.C.) and another in a grave at Abydos (from about 2600 B.C.), both in Egypt. A cube of iron was found in an 1800 B.C. grave at Knossos in Crete. Tombs at Pylos in the Peloponnesian peninsula of Greece contained iron finger rings dating from around 1550 B.C. What was probably an iron dagger was found at the site of Ur of the Chaldees and is believed to date from 3100 B.C. None of the foregoing are believed to have been fashioned from man-made iron. Tools and weapons of man-made iron were discovered at Gerar, near Gaza in Biblical Palestine, and some of the iron knives found there are believed to go back to 1350 B.C.; remains of iron-working furnaces from about 1200 B.C. were also unearthed at this site. The dates given here are only relative, since archeological research is continually turning up new evidence that necessitates frequent revision of chronology.

References made to iron in very ancient writings from China and India suggest that the metal was used in those areas at least as early as 2000 B.C., but there is nothing to indicate that the iron was man-made. Some authorities ascribe the original discovery of practical iron smelting to peoples in India at a very early date.

On the basis of existing evidence, the deliberate smelting of ore to produce iron seems to have begun to be practiced to an ever-increasing extent over a relatively

wide geographic area in the ancient world between 1350 B.C. and 1100 B.C. After the latter date, the art of iron-making seems to have become generally practiced, at least by the more advanced peoples.

It must not be inferred that the peoples of all areas advanced the art of smelting iron to the same degree over the same period of time; isolated peoples in India, Africa, and Malaya, for example, still employ crude iron-smelting processes not unlike those of other more advanced peoples of 3000 years ago. Neither must it be assumed that, as soon as man-made iron became available, iron at once supplanted stone, bronze, brass, and other materials in tools and weapons. In some localities, tools and weapons of both stone and metals were in simultaneous use for some time until the metals completely took the place of stone. Iron gradually and eventually replaced bronze, brass and the other then-known metals wherever the superior properties of iron made it desirable. The properties of bronze and brass, which could readily be melted and cast into shape, depended largely on their chemical composition. The properties of objects made from iron, however, were more dependent upon the care and skill expended in smelting, forging and hardening, as described below.

Products of Ancient Iron Smelting—According to the usual manner in which early smelting processes probably were carried out, the product would be soft, malleable, wrought iron. If the temperature was high enough and the lump of reduced iron, intentionally or unintentionally, was kept long enough in contact with hot charcoal, away from contact with air, the pasty sponge of iron could be made to absorb carbon from the fuel. Absorption of moderate amounts of carbon (up to, say, one per cent) would cause the metal to become capable of being made very hard by cooling rapidly from a high temperature, in a manner comparable to modern steels. "Soft" wrought iron, containing only very small amounts of carbon, cannot be hardened appreciably by such treatment. Carbon might similarly be absorbed during repeated heating of the metal in charcoal forge fires prior to hammering to make a tool or weapon. Carbon could also be added to iron by variations of the crucible and cementation processes discussed in Chapter 13 of this book.

The metal now called "steel," in its simplest form, is essentially an alloy of pure iron with less than 2 per cent carbon. As mentioned above, one of the important properties of iron alloyed with moderate amounts of carbon is its ability to become very hard by rapidly cooling (**quenching**) it from a high temperature, providing that it contains sufficient carbon. This effect evidently was known at an early date. It also was known that the quenched metal, which was very hard and somewhat brittle, could be reheated to a relatively low temperature after quenching to make it less brittle without too drastically lessening the hardness obtained by quenching. This latter process is now known as **tempering**.

Judgment and skill of the operator were the only means of control of any of the early smelting or hardening methods, since nothing was known of the metallurgical principles which governed them. In smelting, the metal was not predictably uniform from one operation to the next, and a large part of the iron in the ore was lost to the slag. This lack of uniformity in the product of the smelting operation made it impossible to employ other than "rule-of-thumb" methods for carrying out the hardening treatment, and failure to obtain the desired results was probably common. In some areas, the iron ores also contained some other metals beneficial to the properties of the iron with which they became al-

loyed during smelting (manganese, for instance), and the metals produced from such ores were so superior as to become justly celebrated, although the reason for the superiority was not then known.

Early Cast Iron—The more carbon an alloy of iron with carbon contains, up to something over 4 per cent carbon, the lower the melting point of the alloy will be. As mentioned earlier, iron reduced from ore in the smelting process could absorb carbon from the fuel in the hearth or furnace if the spongy metal was kept surrounded by the hot charcoal in a location where it was protected from contact with air. It was even possible for at least parts of the "sponge" to absorb enough carbon (say, 2.5 to 3 per cent) so that the melting point of those parts of the metal was lowered to such a degree that molten high-carbon iron was produced. In most cases, the lumps that formed when the liquid metal solidified were thrown away by the early smelters as worthless, since they were not malleable even when heated. Eventually, it was learned how to produce such molten iron deliberately in special types of furnaces, from which it was poured into molds of the desired shapes to make useful articles. Specimens of cast-iron utensils are extant, notably in China, dating back to at least 200 B.C.

As larger and larger smelting furnaces were used, molten high-carbon iron eventually came to be the chief product of smelting. Cast into blocks called **pigs** (whence comes the name **pig iron**) this iron could be remelted as desired for casting into molds, or could be treated by various processes to make wrought iron and steel. Details of wrought-iron manufacture are given in Chapter 11; some early steelmaking processes are described in Chapter 13.

Chapter 2

SOME FUNDAMENTAL PRINCIPLES OF CHEMISTRY AND PHYSICS

PART 1 — THE COMPOSITION, STRUCTURE AND PROPERTIES OF MATTER

SECTION 1

THE RELATION OF METALLURGY TO PHYSICS AND CHEMISTRY

In principle, steelmaking involves only a relatively few, outwardly simple steps (Figure 2—1). The principal iron ores used in the United States consist of combinations of iron with oxygen (iron oxides), mixed with varying percentages of useless earthy materials. In order to remove the oxygen and useless materials, the iron ore along with coke and limestone are charged into the blast furnace. Hot air blown into the blast furnace burns the coke to generate heat. The hot carbon of the coke, and the carbon-bearing gases generated by its burning, combine with the oxygen of the iron oxide, leaving the iron in metallic form. The iron, in the molten state, collects in the hearth at the bottom of the blast furnace. The limestone combines with the useless part of the ore to form molten slag that floats on top of the pool of molten iron. In this process, the iron becomes contaminated with some of the carbon from the coke used as fuel. The product of the blast furnace, pig iron, may contain somewhat over 4 per cent carbon. To make steel from pig iron, some of the carbon must be removed, because most steels contain considerably less than 1 per cent carbon. The unwanted excess of carbon is removed in the steelmaking processes, principally the Bessemer converter and the open-hearth furnace processes, using controlled amounts of oxygen for its removal. The resulting final product, steel, is first poured into molds to form ingots, which then are formed into useful shapes by rolling or other forming processes. Where very complicated shapes that cannot be rolled or forged are required, the molten steel may be poured into molds that give it the shape in which it is to be used without any further forming; such shapes are called steel castings. However formed, the final products, in a great many

cases, are subjected to heat treatment to develop special properties.

The procedures simply outlined above become complex in practice because of a vast array of complicating circumstances. Actually, the problems in each step of manufacture are very complex. Their solution requires considerable technical knowledge and ability. Some previous knowledge of the fundamental sciences of Chemistry and Physics is essential to a study of these problems. The purpose of this chapter is to present, in as concise and simple a manner as possible, those principles of these two sciences that are directly related to the manufacture of iron and steel.

Physics and Chemistry are related sciences, since both are concerned with the properties of material things (collectively called matter, which may be defined as anything that occupies space). Physics is concerned chiefly with the structure and behavior of matter, and with energy in its various forms, whereas Chemistry is devoted to study of the composition of different kinds of matter and the ways in which they interact with each other. The two sciences overlap to such an extent that, in recent years, two new sciences known as Physical Chemistry and Chemical Physics have arisen on the middle ground.

The science of Metallurgy is based on the two fundamental sciences, Physics and Chemistry, and is commonly subdivided into two major fields; namely, Physical Metallurgy which deals with the structure, fabrication and behavior of metals, and Process Metallurgy (also called Chemical Metallurgy) which deals with the smelting of ores and minerals and with the refining and furnace reactions of molten metals.

SECTION 2

COMPOSITION OF MATTER

The Nature of Matter—Matter is the basic working material in the world, and it is associated with all human activities in some way. The human intellect is aware of the existence of material things (things composed of matter) through the senses of sight and touch. Although it is difficult to accurately define matter, cer-

tain facts about it are plainly evident. For example, it occupies space, it is acted upon by the force of gravity, and it possesses certain properties that are dependent upon its composition and structure. Matter which occupies a limited portion of space is termed a body or mass.

STEEL MAKING

FROM RAW MATERIALS TO FINISHED PRODUCTS

FIG. 2-1. The principal steps in making finished steel products from the primary raw materials (iron ore, coal, limestone).

Mixtures, Compounds and Chemical Elements—Most materials in nature are mixtures; that is, they are composed of a commingling of different kinds of matter. The various kinds of matter in a mixture are called its components or ingredients. For example, iron ore may be a mixture of iron oxides, sand, and clay, and it is possible, by mechanical means, to separate a sample of the ore into these ingredients. It is typical of mixtures that they may contain any proportion of ingredients.

Any material, when sufficiently purified so as to consist of only one kind of matter, is spoken of as a substance. Substances, unlike mixtures, always contain the same ingredient or ingredients, and possess definite and invariable physical and chemical properties.

Most of the many thousands of pure substances known to the chemist can, with greater or less difficulty, be broken down into simpler substances by chemical means; that is, they can be decomposed into simpler substances by:

- (1) The action of heat.
- (2) Electrolysis, or the action of an electric current.
- (3) Chemical reaction with other substances.

However, there is a group of 98 different substances which cannot be decomposed by chemical means. These 98 substances are the chemical elements, usually simply called elements or elementary substances.* All other known substances are made up of various combinations of two or more of these elements; such combinations are called chemical compounds. It has been estimated that about 99 per cent of the solid crust of the earth is made up of a multitude of chemical compounds composed chiefly of only twelve of the chemical elements, approximately as follows:

Element	Per Cent
Oxygen	49.85
Silicon	26.03
Aluminum	7.28
Iron	4.12
Calcium	3.18
Sodium	2.33
Potassium	2.33
Magnesium	2.11
Hydrogen	0.97
Titanium	0.41
Chlorine	0.20
Carbon	0.19
TOTAL	99.00

A chemical compound is a distinct substance formed by a union of two or more elements in definite proportions. Each compound always contains the same elements, united in the same proportions by weight.

Symbols of the Chemical Elements—For convenience and brevity, each element is represented by a symbol. These symbols are composed of the first letter, capitalized, of the English or Latin names of the elements, combined, where necessary as a distinguishing mark, with some succeeding letter. Thus, C = carbon, Ca = calcium, Cd = cadmium, F = fluorine, Fe = ferrum (iron), and so on.

Broad Classification of Chemical Elements—A study of the elements reveals the fact that they consist of two great classes; namely, those that combine with oxygen and hydrogen to form bases, and those that combine with oxygen and hydrogen, or hydrogen alone, to form

acids. The former are sometimes called metals and the latter non-metals, or metalloids. The line of division is not a sharp one. Some elements, called amphoteric elements, form either acids or bases, according to the type of chemical change involved, but the tendency is usually more pronounced in the one direction than in the other. Furthermore, like plants or animals, these two main divisions may be subdivided into families or groups, the members of which possess similar properties. These divisions and groups are discussed in a later section of this chapter.

There are 77 elements classified as metals on the above basis. All of these are solids at ordinary pressures and temperatures, except mercury (Hg), which is liquid. The metals generally conduct heat and electricity well. Many of them are malleable; that is, they can be rolled or hammered into desired shapes without rupturing. The more malleable metals can be rolled or hammered into thin sheets more easily than others. Many metals also are ductile. Ductility permits metals, when pulled, twisted or stretched beyond a certain point, to alter their shape permanently without breaking (unless the stress causing the deformation is too continued and too great, in which case, the metal will deform to the greatest possible extent in an effort to accommodate the load imposed on it, after which it will fracture). The remaining 21 elements classified as non-metals are either gases or brittle solids at room temperature and under atmospheric pressure, with the exception of bromine which is a liquid under these conditions.

Atoms and Molecules—Centuries ago, Greek philosophers evolved the concept that all kinds of material things are made up of tiny particles which they called atoms (Greek: indivisible). They assumed incorrectly that there were as many different kinds of atoms as there were different kinds of natural substances. It was not until the latter half of the Seventeenth Century that the British physicist Boyle defined the term "element" in almost its modern sense and, in conjunction with the work of others, established the concept that all natural substances, however complex, are composed of various combinations of two or more elements, and that there can be only as many kinds of atoms as there are elements. The different atoms can combine to form compound atoms, now generally called molecules (Latin: a small mass). Even atoms of the same element can and do combine to form molecules. Some few elements, such as the inert gases, are called monatomic elements because they are composed of single, uncombined atoms.

The British chemist Dalton, in 1808, propounded a very important hypothesis, now known as the atomic theory, to explain certain phenomena associated with chemical changes. This hypothesis is based upon the following assumptions.

1. The molecules of matter are themselves made up of small particles called atoms.
2. Atoms possess the power of attracting other atoms or otherwise attaching themselves to them.
3. Atoms do not subdivide in ordinary chemical changes.

Based on the foregoing reasoning, an atom may be defined as the smallest part of an element that ever takes part in a chemical reaction. A molecule may be defined as the smallest particle of an element or a compound that has the chemical properties of larger samples of that substance. A molecule may contain one or an unlimited number of atoms of the same or different elements. Two or more simple molecules, all alike, may combine to form what is called an associated molecule; in some substances, this may produce molecules con-

*Since this chapter was written, the discovery of Elements 99, 100 and 101 has been reported.

taining so many simple molecules that the associated molecule becomes a **giant molecule** or, as giant molecules are sometimes called, a **macromolecule**.

Until relatively recently, it was thought that all atoms of the same element had the same mass or weight, the same form, and the same combining power, while atoms of other elements differed in one or more of these respects. As will be learned in the discussion of atomic structure that follows, this supposition is now known not to be precisely true, but it forms the best approach to a practical use of Chemistry.

Atomic and Molecular Weights—As will be learned later in this chapter, Dalton established that, when elements combine with each other, a definite weight of one element **always** combines with a definite weight of the other. For example, 2 pounds of hydrogen will always combine with neither more nor less than 16 pounds of oxygen to form water (H_2O). The definite weights were given the name **combining weights** which were different for each element. The atom is so small that it is useless to hope that its mass or weight will ever be determined by direct individual weighing. However, the weight of one atom of an element must be proportional to the

combining weight of that element. Since the combining mass or weight of hydrogen is the least of all the elements, it is assumed that its atom is the lightest. Therefore, the atomic weight of hydrogen was given a value of "one" by Dalton, and the atomic weights of the other elements became multiples of it. However, in view of the fact that comparatively few compounds are formed by hydrogen with other elements, while oxygen forms the most compounds of any element, it was later decided to make oxygen the standard. Accordingly, the atomic weight of oxygen is made 16, and the atomic weights of other elements are compared with it as a standard, thus making hydrogen 1.008. This system of comparative weights is the basis for the compilation known as the International Table of Atomic Weights. Being relative, it permits calculations in any unit of mass or weight—grams, kilograms, ounces, or pounds. Table 2—I gives the atomic number, atomic weight, melting point and boiling point of the elements.

The **molecular weight** of a compound, for the purposes of this book, may be considered to be the sum of the atomic weights of all of the atoms making up the molecule.

SECTION 3

THE STRUCTURE OF MATTER

Atomic Structure—Each chemical element has definite chemical and physical properties that are different from those of every other element. These properties for any element are determined by the structure peculiar to atoms of that element. Modern physicists have probed deeply into the structure of atoms and, as knowledge increases, it becomes more and more difficult to present a simple description of the probable structure of the atom. Nevertheless, an attempt will be made here to summarize those points that are pertinent to an understanding of how atomic structure affects chemical and physical properties of matter. While there exists a difference of opinion among specialists as to whether the component parts of the atom are discrete particles, electrical charges, or electromagnetic waves, since they exhibit many of the characteristics of each, for the present purposes the components will be considered and referred to as particles for the sake of simplicity of discussion.

Atoms have been stated above to be not subdivided in ordinary chemical and physical changes; in fact, they are nearly indestructible. They are not solid bodies, but possess an open structure that can be penetrated by particles smaller than ordinary atoms if the particles possess sufficient velocity. The structure of the atom may be considered as consisting of: (a) a **nucleus**, surrounded by (b) an **electronic system** at some distance from the nucleus.

The Atomic Nucleus—The nucleus at the center of every atom is dense and nearly impenetrable. As will be shown later, the nucleus is not involved in ordinary chemical or physical changes. While the nucleus of an atom must be very small in size in comparison with the size of the atom as a whole, most of the mass of any atom is concentrated in its nucleus. That portion of the weight of an atom concentrated in its nucleus is called its **nuclear mass**. Two kinds of particles make up the nucleus: **protons** and **neutrons**. Each proton is of unit mass and carries a unit positive electrical charge. Each neutron is also of unit mass, but carries no charge. Unit mass is the mass of a sixteenth part of the most abun-

dant type of oxygen atom (according to physicists) or of an average oxygen atom (according to chemists). The difference is quite small. **Unit positive charge** is equivalent to the positive charge on the nucleus of an atom of hydrogen, equal to 4.802×10^{-10} electrostatic units. Hydrogen has the simplest known atomic structure, having a nucleus consisting of a single proton and an electronic system consisting only of a single electron (a nearly massless particle with unit negative charge, defined more completely below). The charge on the hydrogen nucleus is the smallest that has ever been encountered. The nucleus of every atom carries a positive electrical charge that represents the total of all of the equal unit positive charges on the individual protons that are contained in the nucleus. The total positive charge on the nucleus is independent of the number of neutrons in the nucleus, since the neutrons are not charged. The **atomic number** of an element corresponds to the number of protons in the nucleus and, therefore, to the total number of unit positive charges on the nucleus. The **atomic weight** of an element is determined largely by the weight of the combined number of protons and neutrons in the nucleus (nuclear mass), since each of these types of particles possesses unit mass; the total weight of the electronic system is only a minor part of the weight of an atom.

If a listing of the elements is arranged in the order of increasing atomic numbers, it is observed that the atomic weights do not increase in the same regular way. The atomic numbers and atomic weights of the first 18 elements are given in Table 2—II.

This tabulation clearly illustrates that increases of 1 in atomic number (increases of 1 in the number of protons in the nucleus) do not increase atomic weight by any regular amount.

The Electronic System—Rotating about the nucleus, in orbits at considerable distances from it, are nearly massless particles called **electrons**, each carrying a unit negative charge of electricity. The mass of a proton is somewhat more than 1800 times that of an electron. Besides rotating in orbits around the nucleus, electrons

Argon	A	18	39.944	4.487

are also considered to spin on their own axes. The unit negative charge on each electron is just sufficient to balance or neutralize a unit positive charge such as that carried by a proton. The number of electrons in any atom of an element, since the atom as a whole normally is electrically neutral, must equal the number of protons in the nucleus, and both are numerically equal to the atomic number of the element. An increase of one in atomic number, then, adds one proton (one unit of positive charge) to the nucleus, and adds one more electron to the electronic system rotating about the nucleus. The electrons do not rotate around the nucleus at random distances from it, but are located in successive groups or shells of electrons (often called energy levels). For convenience, these shells have been designated as the K, L, M, N, etc., groups, shown as follows for the first four groups, with the K group closest to the atomic nucleus:

Group	Maximum Number of Electrons in Group
K	2
L	8
M	18
N	32

It is the electrons in the two outermost electron "shells" of its atoms that largely determine the chemical properties of an element. The innermost electronic "shells" and the nucleus are not affected by ordinary chemical changes. The electrons in the two outermost shells are often referred to as valence electrons.

Periodicity of the Elements—The periodic table shown as Table 2—III* is the modern version of a similar table originated (1869) by the Russian chemist Mendeleev. The elements are arranged in horizontal rows in the order of increasing atomic number, with proper reference to the arrangement of the electronic systems of their atoms.

As the atomic numbers of the elements increase, the atomic weights gradually increase (but not in regular increments, as already described). Another property that is related to the atomic number is the character of

the X-rays emitted by the various elements, the rays becoming more and more penetrating as they are emitted from excited samples of elements of higher and higher atomic number. These two properties that increase as the atomic number increases can be explained on the basis of the gradual increase in the charge and mass of the nucleus.

The periodic table derives its name from the fact that the elements that appear in each vertical column of the table are very similar in chemical properties. In following the horizontal rows, it is found that those properties which depend on the outermost electron groups of the electronic system (chemical properties) are periodically repeated for elements in the same vertical columns, as are some qualitative physical properties. The actinide and lanthanide metals are very similar in their chemical properties because the new electrons added as the atomic number increases are being added in inner electron groups, leaving the two outermost "shells" (that largely determine chemical properties) almost unchanged. It is because the nuclear structure of the atom has negligible effect on chemical properties of an element that the new knowledge of atomic structure has not invalidated the various laws and theories that have long been in use for making practical application of chemistry.

Isotopes—Every element (except hydrogen) is characterized by having the nucleus of the atoms composing it made up a definite number of protons and a number of neutrons that is variable within rather narrow limits. Most atoms of the same element have the same number of neutrons, but some do not and, therefore, they differ somewhat in nuclear mass from other atoms of that element. Atoms of the same element which have different nuclear masses are called isotopes. Since isotopes are the effect of variations in the constitution of the nucleus, due to a larger or smaller number of neutrons being present, the electronic system is not affected to any appreciable degree and it is extremely difficult to chemically separate isotopes of the same element. The separation can be effected, however difficultly, by physical means in some cases; for example, by taking advantage either of the slightly higher boiling point (lower vapor pressure) or slightly lower diffusion rate of the heavier isotope.

Summary on Atomic Structure—In summary, an atom

* Based on a table in "General Chemistry," by H. G. Deming, published by John Wiley & Sons, Inc., New York (Sixth Edition, 1932).

has a nucleus made up of protons and neutrons. The number of protons in the nucleus of an atom of a given element is fixed, and determines the number of electrons in the electronic system surrounding the nucleus. These electrons are present in groups or "shells" at various energy levels. The outer groups of electrons in this system determine the chemical properties of an element. Neutrons in the nucleus contribute to the nuclear mass only, and have no significance in ordinary chemical changes. The number of neutrons is not a fixed quantity for many elements, and there are therefore variations in nuclear mass of these elements that result in isotopes.

The number of neutrons needed to give the required nuclear mass to account for the atomic weight can be calculated. Taking the iron atom as an example: the atomic number of iron is 26, therefore, it has 26 protons of unit mass in its nucleus. Since the atomic weight of iron is 56, 56 minus 26 or 30 neutrons, each of unit mass, would be required in the nucleus to account for the atomic weight of iron. Actually, the atomic weight of iron is somewhat less than 56; 55.86 to be exact. Atomic weights are seldom integral numbers because of what is called the "mass defect," a concept too involved for simple explanation.

The electron "shells" of the iron atom (assuming an exact atomic weight of 56) would contain the following numbers of electrons, since a nuclear positive charge of 26 units would have to be balanced by an equal number of negative charges in the electronic system:

Group	Number of Electrons
K (closest to nucleus)	2
L	8
M	14
N	2
Total	26

By using data in the periodic table, Table 2—III, a similar calculation can be made for the atoms of any element.

Physical, Chemical and Nuclear Changes—Matter is constantly undergoing changes. These changes are of three kinds, namely, one in which the nature and composition of the matter undergoing the change remain the same, called a **physical change**, another in which the nature and composition are affected, called a **chemical change**, and a third in which an element may be converted into one or several other elements, called a **nuclear change**. The freezing of water and the fusion of steel are examples of the first, while the burning of coal is an everyday example of the second; the third type of change is exemplified by the decomposition of unstable elements such as radium and polonium to form new elements, through nuclear changes. Nuclear changes can also be brought about through human intervention. Since 1919, when the first nuclear change was produced artificially, more and more powerful means have been devised for "bombarding" atomic nuclei with swiftly-moving particles to alter the number of electrons, protons and neutrons in atoms of one element to convert it into another element. This is the transmutation process, which was dreamed of by the early alchemists, and which was believed to be impossible by modern scientists until quite recently. As far as the chemist and metallurgist are concerned, however, this great discovery does not detract from the importance and usefulness of the concept of the atom as the fundamental unit of matter, since, in all ordinary chemical and metallurgical reactions and processes, the atom is still the smallest subdivision actively involved. Thus, the chemical laws of combination and reaction between elements are still valid, and the chemical and physical properties of substances are still determined by the kinds, proportions, and arrangements of the atoms which combine to form the larger structural units of matter, such as molecules, fibers, and crystals.

SECTION 4

CRYSTALLOGRAPHY

One of the most important characteristics of metals is that they are crystalline. This means that the atoms of a metal are arranged in a regular, three-dimensional, geometrical pattern. Although the crystallinity of gem stones and some other minerals, such as diamond or quartz, is generally evident from their symmetrical external form and optical properties, it is not obvious that metals are crystalline. There are several reasons for this, namely: (1) Metals usually do not solidify from the molten state as perfect, **idiomorphic**, single crystals with symmetrical external shape; instead, they crystallize as aggregates of small, **allotriomorphic** crystals of irregular shape, tightly bound together at the crystal boundaries. In metallurgy, these small allotriomorphic crystals are termed **grains**; (2) These grains are so small that a microscope with a magnification of several hundred diameters is generally necessary to observe them; (3) Metal grains are opaque, so that reflected-light microscopy (termed **metallography**), on a carefully polished and etched cross-section of an aggregate of metal grains, is required to see the individual grains; and (4) Since the metal grains are opaque, even in thin sections, their optical properties, which are a direct manifestation of crystal structure, cannot be readily measured, as in the case of crystals

of minerals and chemical compounds that can transmit light, each in its own characteristic manner; instead, more penetrating radiation (X-rays or electrons) must be used to measure the crystal characteristics of metals. The study of the characteristics of crystals is known as **crystallography**.

The physical and mechanical properties of metals and other crystalline materials are dependent to a large extent on their particular crystal structure and to imperfections which may exist in that structure. This is the most important reason for studying crystal structure. A second reason for investigating crystal structure both in metallic and non-metallic materials is that no two known chemical substances or elements have exactly the same crystal structure. Even though the geometrical arrangement of atoms may be the same, the distances between atoms will be different. Thus, crystal structure provides a powerful method for distinguishing between various compounds or elements, even in cases where they are chemically identical. For example, gamma iron and alpha iron are both polymorphic forms of the element iron, and therefore have the same chemical constitution; also, calcite and aragonite are polymorphic forms of calcium carbonate (CaCO_3). However, their crystal structures are quite different, so

that they can be identified by this property. In this manner, the determination of crystal structure becomes an important method in qualitative and quantitative analysis.

In order to understand investigations of the crystal structure of metals and other materials, it is necessary to define some of the terms and quantities commonly used in crystallography. The concept encountered most frequently is that of the **unit cell**, which is the basic unit of crystal structure. A unit cell is a small grouping of atoms or molecules, which if repeated indefinitely in three dimensions will result in the development of the crystal. The unit cell, therefore, exhibits all the properties of the large crystal, and it is only necessary to know the structure of the unit cell in order to specify the structure of the whole crystal.

One of the quantities used to specify crystal structure is the **space lattice** or **Bravais lattice**. If imaginary straight lines were drawn between the atoms of a crystal, these lines would form a lattice dividing the space into equal-sized prisms standing side by side with all faces in contact so that no voids would exist. This lattice of lines is called a space lattice and is of fundamental importance in crystallography. The intersections of the lines are called the points of the space lattice. The manner in which the reference lines are drawn is arbitrary, and in many cases it is found convenient to draw the prism so that points are at the centers of the prism faces or in the center of the prism. A space lattice has two important characteristics; the first of these is that, if a straight line is drawn through two adjacent lattice points and continued on at regular, periodic intervals, points identical to the first two will be encountered; the second is that every point in the space lattice has identical surroundings. This second characteristic means that the group of points surrounding a point of the lattice is the same for every lattice point. There are 14 space lattices, shown in Figure 2-2, and it can be proven mathematically that no others can exist, that are not equivalent to all or part of one of these fourteen.

It can be seen that the points of each of the space lattices can best be identified by reference to a set of three coordinate axes. These axes may or may not be of equal length, and may or may not be at equal angles to

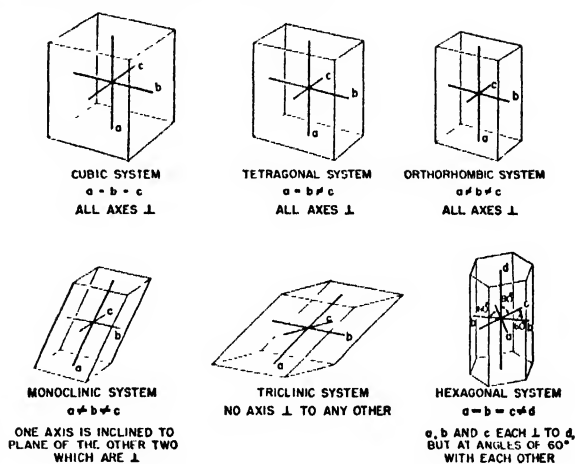

FIG. 2-3. The six symmetry types of crystals.

each other. There are six such sets of axes commonly used. These axes define the six crystal systems shown in Figure 2-3. Frequently, seven crystal systems are defined, by adding what is known as the rhombohedral system, in which the lengths of the axes are all equal and the angles between the axes are equal, but different from 90° . However, the rhombohedral axes can always be converted to hexagonal axes, making their inclusion as a separate crystal system unnecessary. The degree of symmetry of a crystal might be loosely defined as the number of ways in which the unit cell can be rotated, or atoms can be transposed, across some axis or central point, without altering the crystalline arrangement. On this basis, it is interesting to note that the six crystal systems decrease in symmetry in going from cubic to triclinic systems, with the hexagonal system occupying a position between the cubic and tetragonal systems.

Space lattices and crystal systems lead to only a partial description of the crystal structure of a metal or other crystalline solid. If the complete structure is to be specified, it is necessary to consider also the **symmetry classes** and ultimately to determine the proper **space group**. There are 230 possible space groups; however, there are a very large number of crystal structures, since the space group defines only the geometrical arrangement of the atoms and not the distances between atoms. When both the space group and the interatomic distances are known, the crystal structure is completely determined.

Since the atoms in a crystal are arranged in a regular fashion, it is evident that planes can be defined which will contain many atoms. The simplest such planes are those containing two axes of the coordinate system used to define the crystal system. Other planes will, of course, be more complex; their existence, however, should be obvious. These planes are of the utmost importance in discussing properties of a crystal such as its orientation, twinning habit, and slip system. Therefore, some system of nomenclature is necessary to distinguish these planes and to define their orientation, but not their position. The system of nomenclature universally used is that of **Miller indices**. As stated above, it is convenient to define three coordinate axes to describe the crystal system. Beginning at the intersection of these axes and proceeding along any one of them, identical points will be found to occur at periodic intervals, with one of these intervals in each direction defining the unit cell. To

FIG. 2-2. The fourteen general patterns of unit cells. All types of crystal space lattices can be formed from these unit cells.

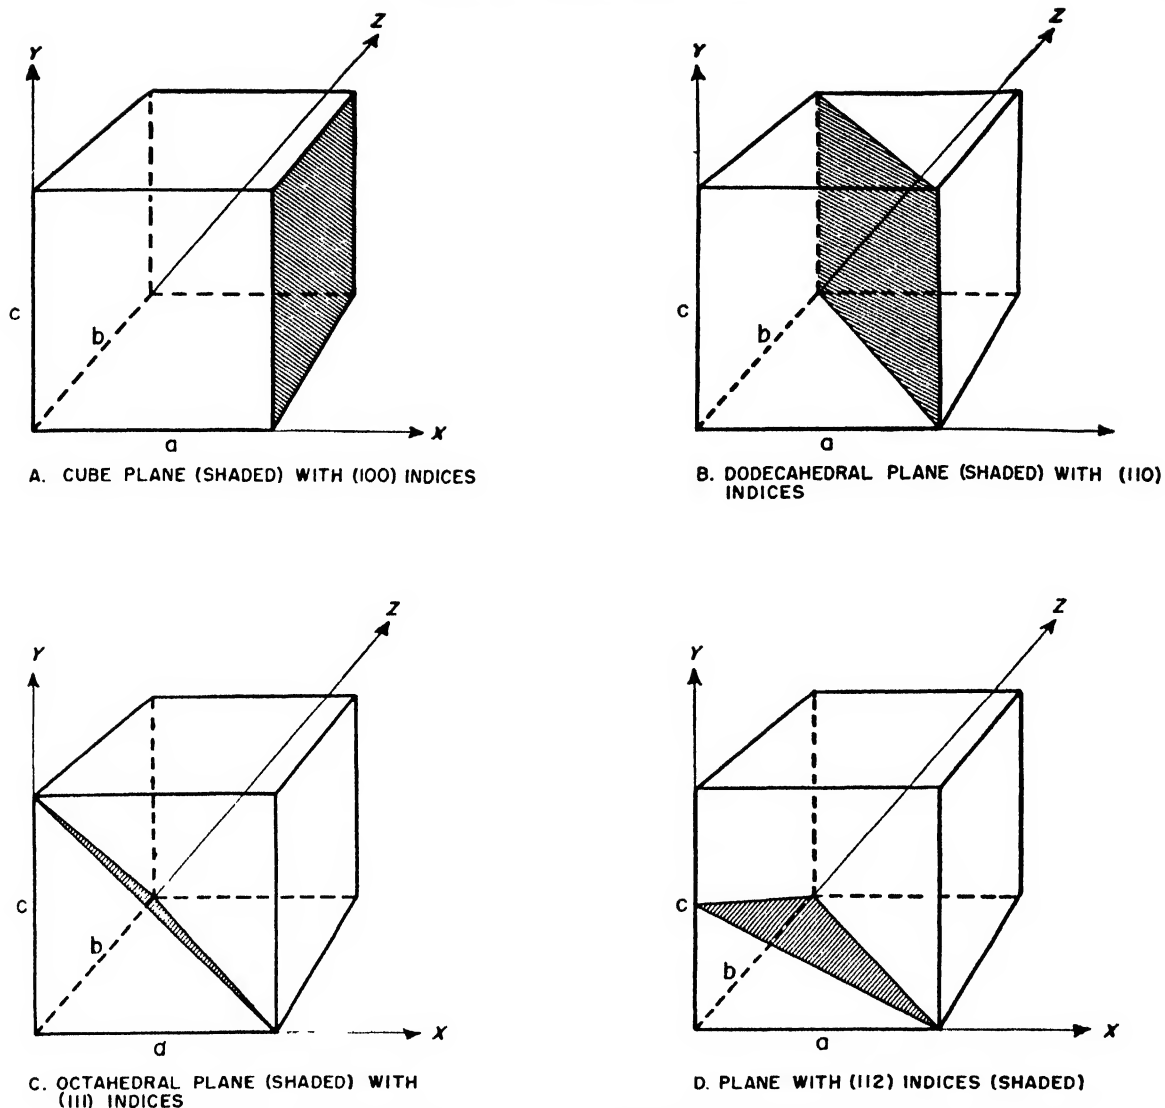

FIG. 2-4. Planes with various indices in cubic crystal.

determine the Miller indices of a plane, it is necessary first to find its intercepts on the three coordinate axes X , Y , and Z in terms of multiples or fractions of the unit cell edge a , b , and c . The values of a , b , and c are known as the **lattice parameters**. If a plane is parallel to one or more axes, the intercept is taken as infinity. The reciprocals of these three numbers are taken, and the reciprocals are reduced to the three smallest integers having the same ratio. These integers, written in parentheses are the Miller indices of the plane. For purposes of general discussion, the letters "h," "k" and "l" are used to represent these integers, thus: (h,k,l) . In an actual example, where a plane intersects the X -axis at three units, the Y -axis at one unit, and the Z -axis at infinity, the intercepts are 3, 1, ∞ , and the reciprocals of the intercepts are $\frac{1}{3}$, 1, 0; when multiplied by 3, these give Miller indices of (1, 3, 0), corresponding to (h,k,l) of the general case. As a result of the reduction to the smallest integers, parallel planes will have the same indices. Figure 2-4 shows some of the important crystal planes with their Miller indices. It should be noted that the coordinate axes extend in both the positive and

negative directions from their intersection, so that negative indices are also possible.

Direction indices are also frequently used in crystallography to specify the direction or orientation of a line in the crystal. If a point is moved from the intersection of the coordinate axes (the **origin**) to some other position in the crystal by means of translations parallel to the coordinate axes, the direction indices of the line joining the origin and the final position will be numbers u , v and w , where u is the number of units of a that the point moved parallel to the X -axis, v is the number of b units that the point moved parallel to the Y -axis, and w is the number of c units that the point moved parallel to the Z -axis. The values of u , v , and w are reduced to the simplest integers, and are written in square brackets $[u, v, w]$ to indicate that they are direction indices. For example, in Figure 2-4, the face diagonal of the base of the parallelepiped will have the direction $[110]$, the X -axis will have the direction $[100]$ and the body diagonal $[111]$.

These definitions of the important terms and concepts will enable us to discuss the crystal structures of the

various metallic elements. The term **crystal structure** will be used in the following discussion to cover all of the descriptive information, such as the crystal system, space lattice, symmetry class, space group and distances between atoms (**lattice parameters**), necessary to completely define the crystal structure. Fortunately, metals crystallize in simple structures with a high degree of symmetry; in fact, nearly all metals belong to either the cubic, hexagonal or tetragonal crystal systems.

The simplest crystal structure found in nature is the **body-centered cubic structure**. The atomic arrangement is shown in Figure 2—5a; it is evident that atoms are located at the corners of a cube, and one in the center of the cube. Since the corner atoms are shared by adjacent unit cells in a crystal where this atomic arrangement is repeated indefinitely, only $\frac{1}{8}$ of each of the atoms at the corners is contained in the unit cell and the unit cell is said to contain two atoms. This body-centered cubic arrangement is the structure of metallic iron (α iron) at temperatures below about 1650° F. In iron, the unit cell is 2.861 Angstroms long on each edge; the three lattice parameters are of equal length in the cubic system, that is, $a=b=c$. (One Angstrom unit equals 10^{-8} centimeters.) Other elements having this same crystal structure, with different lattice parameter, include chromium, columbium, potassium, tungsten, and molybdenum.

Another simple crystal structure encountered in metals is the **face-centered cubic arrangement** shown in Figure 2—5b. Atoms in this structure are located at the corners of the cubic unit cell and at the centers of the cube faces. Due to the sharing of atoms by adjacent cells, as mentioned above, the unit cell contains four atoms, since $\frac{1}{8}$ of each of the corner atoms and $\frac{1}{2}$ of each of the 6 atoms in the cube faces are in the cell. Iron has this structure (γ iron), with a lattice parameter of 3.63 Angstroms, from a temperature of 1650° F to near the melting point. From about 2600° F to the melting point at 2800° F, iron reverts to the body-centered cubic form (δ iron). Other metals with the face-centered cubic structure include silver, gold, aluminum, copper, nickel, and lead. The face-centered cubic structure is sometimes referred to as the **cubic close-packed structure** because the atoms, if considered as large solid spheres, are arranged so that the total void volume between the spheres is as small as possible. On the (111) planes, the atoms are in intimate contact, and are packed together in the closest possible manner.

A second close-packed structure commonly found in metals is the **hexagonal close-packed arrangement** shown in Figure 2—5c. Crystals having this structure are built up of layers in which atoms are arranged at the six corners and at the center of a regular hexagon. Alternate layers are shifted to permit the atoms of the second layer to fit into the depressions between atoms of the first layer, resulting in the closest possible packing of atoms. The simplest possible unit cell for this structure is a rhombohedron containing two atoms; however, for convenience, the unit cell is usually chosen as the hexagonal prism shown. This unit cell contains three of the rhombohedral cells and is described therefore as being **triply primitive**. Among elements having this structure are zinc, cobalt, beryllium, magnesium, cadmium, titanium and most of the rare earths.

The crystal structure of white tin is not among the three basic types described above; however, because of the importance of tin in the steel industry, its crystal structure will be described. As shown in Figure 2—6 the unit cell is tetragonal with the a and b axes of equal length, and about twice as long as the c axis. In addition to the atoms at the corners, there is one at the center

of the cell and one in each of the side faces; however, the atoms in the side faces are not in the center of these faces.

These relatively simple crystal structures are sufficient to describe nearly all of the solid elements and many compounds. However, more complex unit cells are required to describe the structure of other inorganic, metal-organic, and organic compounds. Oxides, sulphates and silicates of metals, for example, are frequently in lower symmetry systems such as the orthorhombic, monoclinic, and triclinic.

Lattice Imperfections—The foregoing discussion has been in terms of ideally perfect crystals where atoms are located only at proper crystal sites and all such sites

are filled with the proper kind of atoms. In real crystals, particularly metals, this is not usually the case; rather, the lattice has numerous flaws or imperfections. The most common imperfections are **interstitial** or **substitutional** atoms of an impurity or alloying element. By interstitial atoms are meant atoms which fit into the holes or interstices between the atoms of the normal structure. Substitutional atoms are those which replace normal atoms in lattice positions. In either case, the impurity or alloying atoms cause a distortion of the lattice, which may markedly affect the physical and mechanical properties; the changes in properties may be either beneficial or deleterious, depending on the property and the application of the material. The second most common imperfections are **dislocations**, which occur when, in two adjacent rows of atoms in the crystal, one row contains one more atom (or one less) than the neighboring row. It is easy to see that this situation will also produce a distortion of the lattice. As a result of thermal fluctuations, dislocations move through the crystal lattice until they are stopped by another dislocation or some other stress barrier. It is these concentrations of dislocations that are responsible for many of the properties of metals such as **strain hardening**, **slip**, and **internal friction**. In fact, the effect of the imperfections in metals is so important that the study of imperfections has developed into a field nearly as large as the study of crystal structure. However, this field is highly theoretical at present, and any detailed discussion of the effect of imperfections is beyond the scope of this section.

SECTION 5

FUNDAMENTAL CHARACTERISTICS OF MATTER

Length, Mass, and Time—In order to describe the fundamental characteristics of matter, and natural phenomena in general, on a reasonably scientific basis, scientists and engineers everywhere must agree on a common terminology in which words and terms are given precise and limited meanings. Furthermore, it is essential to have a system of standards for accurate quantitative measurements, in which the units are defined as exactly and clearly as possible.

Possibly the most fundamental of physical concepts are length, mass, and time, since combinations of these can be used to express all other physical quantities. Scientific workers generally use the **metric system of units** to describe mass and length. The fact that this system is naturally adapted to the expression of measurements in terms of decimals is of great convenience. In this system, the meter (100 centimeters) is the unit of length and the kilogram (1000 grams) is the unit of mass. In nearly all countries, except England and the United States, the metric system is used for everyday as well as scientific purposes. The **English system** is in common use in this country, but legally the inch and pound are now defined in terms of the meter and kilogram.

The unit of length, the **meter**, was originally intended to be one 10-millionth of the distance from the equator to a pole of the earth, although more accurate measurements made since that time show that this is not strictly true. The standard of length now in use is the **International Prototype Meter**, which is the distance, at 0° C (32° F), between two fine parallel lines on a bar carefully prepared and preserved at the International Bureau of Weights and Measures at Sevres, France. An

accurate duplicate standard is maintained at the National Bureau of Standards in Washington, D. C. In the United States, according to law,

1 inch = exactly 2.54 centimeters or 0.0254 meters
1 foot = 0.3048 meters
1 meter = approximately 39.37 inches

By the mass of a body, is meant the quantity of matter it contains, which obviously will be the same anywhere in the universe. The arbitrary unit of mass is the **International Prototype Kilogram**, a block of platinum-iridium alloy carefully preserved at Sevres, France, which was intended to be exactly equal to the mass of 1,000 cubic centimeters of water at its temperature of maximum density (39.2° F or 4° C), but actually differs from this by a very small amount. A duplicate standard is kept at the Bureau of Standards.

It is essential to distinguish between the mass of a body and its weight. By the **weight** of a body is meant the force with which it is attracted toward the earth. The concept of force is intuitive and is frequently associated with the sense of muscular effort in pushing or lifting various objects. From Newton's law of gravitation, this force of attraction of the earth for a body (its weight) is given in the metric system by:

$$W = gM$$

where "M" is the mass in kilograms, "W" is the weight in Newtons, and "g" is the gravitational attraction at the object's position, and its numerical value on the earth's surface is approximately 9.80 meters per second per second. In the English system, the unit of mass has no special name, the weight is expressed in pounds, and "g" is

approximately equal to 32 feet per second per second. A typical equal-arm balance (no springs) compares the mass of an object with a standardized set of masses and will give accurate mass values anywhere. Of course this also measures the relative weights, but in order to obtain the actual or absolute weight of the object, the value of "g" at the place of measurement must also be known, since the value of "g" decreases as the distance of the object from the center of the earth increases. However, since "g" varies only slightly over the earth's surface, the weight of the object can be estimated for most practical purposes by using such a balance, even though "g" is not actually measured. If a simple spring balance could be accurately calibrated at one location, it would give accurate weight values everywhere else, since it measures directly the attractive force of the earth on the object.

All measurements of time are based on the time required for the earth to make one rotation on its axis. Astronomers use *star time* in which one rotation with respect to the fixed stars is 24 hours. For civil and most scientific purposes, *mean solar time* is used, in which 24 hours, or 1,440 minutes, or 86,400 seconds is the average time for one rotation of the earth on its axis with respect to the sun. The unit of time is the second, and this is the same in both metric and English systems.

In dealing with formulas and equations, it is essential not to mix different units of measurement; that is, English units should not be mixed with metric units, and the denomination of the units should be kept consistent (gram-centimeter-second or kilogram-meter-second).

States of Matter—From a casual examination of the surroundings, it is evident that matter may exist in three fundamental states: gaseous, liquid, and solid. A substance may exist in all of the three states; for example, water may exist as a gas (steam), as a liquid, and as a solid (ice). A gas has no definite size or shape, but merely a definite mass; it is composed of molecules or single atoms, which are relatively far apart and free to move because the binding or attractive forces between them are very weak. A liquid has definite mass and volume, but not form; it is composed of molecules or single atoms, which are closely packed together but still are mobile because the attractive forces between them are weak. A solid has definite mass, volume, and shape; it is composed of atoms which are closely situated, tightly bound together, and arranged in a systematic pattern which is known as a crystal structure. Liquids and gases are called fluids on account of their ability to flow. In many cases, they obey the same physical laws. They are distinguished from each other by their relative compressibility: liquids are but slightly compressible, while gases are highly compressible. The volume of a gas can be decreased by the application of pressure; that is, the volume of an ideal gas varies inversely as the applied pressure (Boyle's Law).

Changes of State—It has been stated previously that certain substances can exist in all three physical states; thus, water may exist as steam, liquid, or ice, depending on the pressure and temperature. The state of a substance depends only on the pressure and temperature to which it is subjected. Under ordinary atmospheric temperature and pressure, most substances exist only in a single state; for example, steel is solid at room temperature, and carbon dioxide is ordinarily a gas. However, by applying heat to steel it may be converted to the liquid state (molten steel), and by applying pressure and withdrawing heat, gaseous carbon dioxide may be converted to the solid state (dry ice). The usual sequence of changes of state is: solid \rightleftharpoons liquid \rightleftharpoons gas; how-

ever, some solid substances may be changed directly to the gaseous state, and vice versa, without passing through the liquid state. Changes of state are usually reversible, that is, a solid substance that can be melted by applying heat, can be solidified by withdrawing heat or cooling.

The various changes from one state to another have certain names, thus:

Solid to liquid = melting or fusion

Liquid to solid = freezing or solidification

Liquid to gas = evaporation, vaporization, or boiling

Gas to liquid = condensation

Solid to gas = sublimation

Gas to solid = condensation

Under atmospheric pressure, the temperatures at which these changes occur are characteristic of a particular substance; thus, the melting point of ice (or the freezing point of water) is zero degrees Centigrade, while the boiling point of water (or the condensation point of steam) is one hundred degrees Centigrade. Associated with each change of state there is a transfer of a certain specific amount of energy between each substance and its surroundings. Thus, when a gram of water at 100° C (212° F) evaporates into steam it absorbs 540 calories * of heat energy, and when a gram of steam at 100° C condenses to water, it releases this same amount of heat energy. Also, a gram of water at zero degrees Centigrade gives off 80 calories of heat energy when it freezes into ice, and when a gram of ice melts into water it absorbs the same amount of heat energy. The heat energy involved in the process of melting or freezing is termed the *heat of fusion*; this amount of heat must be added merely to change the material from the solid state to the liquid state, and the temperature of the material undergoing melting remains constant until sufficient heat has been absorbed to effect the change of state. Heat of fusion is usually expressed in "calories per gram," "kilogram calories per kilogram," or "Btu * per pound." The heat absorbed or given off on evaporation or condensation is termed the *heat of vaporization*. Expressed in the same units as those for heat of fusion, heat of vaporization absorbed by a liquid substance represents the quantity of heat required to change the liquid to the vapor state at the boiling point without increasing the temperature of either the liquid or the vapor.

Vapor Pressure—The tendency of a liquid to evaporate is measured in terms of its vapor pressure; that is, when the molecules of the liquid exert great pressure against the surrounding atmosphere, and have a great tendency to jump from the liquid surface into the air (evaporate), the vapor pressure is large and the boiling point is relatively low. The vapor pressure of a liquid, then, is the pressure exerted by the liquid at a given temperature under the conditions that give liquid-vapor equilibrium. For example, if a liquid is boiling in an open container, then the vapor pressure of the liquid at the boiling temperature must be one atmosphere. At a temperature less than the boiling point, the liquid exerts a vapor pressure less than atmospheric pressure. Solids usually exert low vapor pressures. The vapor pressure for any material increases rapidly with the temperature. The relationship between vapor pressure and temperature for most materials can be found in the literature.

Electrical Conductivity—The use of matter to conduct electricity is of almost inestimable value. Metals are

* "Calorie" and "Btu" are defined under "Measurement of Heat" in Section 3 of Part 3 of this chapter.

notably good conductors of electric current, whereas other substances, such as glass and quartz are non-conductors or insulators. The electrical conductivity of a substance is determined by measuring the amount of current that will pass through a given volume of the substance in a certain time when a standard driving force or difference of electrical potential is applied to opposite ends of the piece. The electrical conductivity of the various metals differs considerably; thus, the conductivity of copper is about eight times greater than that of iron.

Density—In handling pieces of different kinds of matter, such as wood and steel, it is at once evident that pieces of about the same size (volume) weigh differently, that is, have different mass. In order to express this difference more definitely, the concept of density is useful. The density of a material is its mass per unit volume; expressed mathematically,

$$D = \frac{M}{V}$$

where "M" is the mass measured in grams, "V" is the volume expressed in cubic centimeters, and "D" is the density expressed in grams per cubic centimeter. In English units "M" may be measured in pounds and "V" in cubic feet; the density then is expressed in pounds per cubic foot. This idea of mass or quantity of matter per unit volume is of course applicable to all three states of matter, solid, liquid, and gaseous. Since the volume of a given mass of material depends on the temperature and pressure acting on it, particularly in the gaseous state, it is necessary to specify these two conditions in giving density values. For gases, a standard set of conditions is used, namely, 0° C (32° F) and the pressure exerted by a column of mercury 76.0 centimeters (29.92 in.) high; these conditions are called normal temperature and pressure (abbreviated NTP).

Specific Gravity—It is oftentimes convenient to express the mass (or weight) of a material in terms of the ratio of its weight to that of some standard substance. This ratio between the weight of a body and the weight of an equal volume of a standard substance is termed specific gravity. For liquids and solids, the standard substance is water; for gases, it is hydrogen or air. Since the volumes of both the body and the standard substance vary with temperature and pressure, it is necessary to specify these conditions for both substances. For solids and liquids, only the temperature is usually specified, since the pressure is assumed to be normal. For gases, the conditions usually are normal temperature and pressure. It is necessary to state which standard is used, since air is much heavier than hydrogen.

Elasticity—When a thin strip of steel is bent moderately and springs back to its initial shape when released, it exhibits the property of solid matter called elasticity. Virtually every solid object is elastic, that is, when bent, compressed, twisted, or otherwise deformed, it develops internal force which tends to restore it to its initial form; the deformation is termed the strain and the force developed is called the stress. Different substances develop different stresses for a given strain, that is, they exhibit different ratios of stress to strain (elastic moduli) which are more or less characteristic of the substance. If the deformation of an object is carried to such an extent that it will not resume its initial form when the applied force is removed, the elastic limit of the material is said to have been exceeded. Within the elastic limit, the stress is proportional to the strain (Hooke's Law). Elasticity is very important in metal-

lurgy and engineering and will be discussed more thoroughly in Chapter 49 of this book, devoted to mechanical testing.

Plasticity—The capacity of a solid body to be strained beyond its elastic limit, and thus to suffer permanent deformation, or change of shape, without fracture, is termed plasticity; it is closely related to other important mechanical properties of solid matter, such as ductility and malleability. Substances vary widely in the amount of permanent deformation that they can withstand before fracture; however, specific measures of this property depend not only on the nature of the substance but also on the temperature, speed of deformation, and the geometry of the stress system.

Tensile Strength—When a substance is stretched progressively, a point is ultimately reached where the stress developed overcomes the cohesive or binding forces tending to hold the material together, and the substance pulls apart; in the case of metals, the relationship between the apparent and true force required to fracture the substance is discussed in Chapter 49, and the exact meaning of tensile strength is defined. Tensile strength is more or less characteristic of a substance, but it depends to an important degree on the condition and plasticity of the substance, the temperature, speed of stretching, and shape of the body.

Hardness—The ability of a substance to resist penetration or, in the case of some substances, to withstand wear or abrasion is termed hardness. This is a rather complex association of two or more simpler properties of matter and is closely related to other mechanical properties, such as tensile strength.

As in the case of elasticity, plasticity, tensile strength and hardness will be discussed more fully in Chapter 49 of this book, dealing with mechanical testing.

Viscosity—The resistance of liquids, semi-solids, and gases to movement or flow is termed viscosity, and it is due to internal friction among the molecules constituting the substance. Viscosity varies widely, depending on the substance; thus, oils and sirups are very viscous, whereas water and alcohol are not so viscous. Gases are only about one-thousandth as viscous as typical liquids, such as water. Viscosity is affected to a marked extent by temperature; in general, the higher the temperature, the lower the viscosity of a fluid. Viscosity is usually measured by the time it takes a given amount of the fluid to pass through a long tube of standard diameter, when there is a standard difference in pressure between the two ends of the tube.

Semi-solids, such as tar, may be thought of as extremely viscous liquids. True solids also exhibit a property very much like viscosity in fluids, thus, the vibrations of a tuning fork die out faster than can be accounted for by the rate at which its energy is given to the surrounding air. In the case of solids, this property is known as internal friction or damping capacity.

Specific Heat and Heat Capacity—The specific heat of a substance is the quantity of heat required to raise the temperature of a unit mass of the substance one degree. The value of specific heat changes with temperature, so that an average value must be used that corresponds to the temperature range involved. The heat capacity of a body of a substance between two temperatures is the quantity of heat required to be added to or extracted from the body, respectively, to raise or lower its temperature the number of degrees between the higher and lower temperatures.

Thermal Expansion—It is a matter of common observation that most substances expand when heated and contract when cooled; a property of matter known as thermal expansion. Over moderate ranges of tempera-

ture, the change in length of a piece of material is proportional to the temperature change. It is also apparent that the change in length is proportional to the initial length; that is, the longer the piece, the greater the change in length. The change in length per unit of length, for a given change in temperature, is named the **thermal coefficient of linear expansion**. This quantity is more or less characteristic of a substance and differs greatly for different substances.

Thermal Conductivity—The ability of matter to conduct or transmit heat is referred to as thermal conduc-

tivity. All solids, liquids, and gases conduct heat, but enormous differences exist in the rates at which heat is transferred through them under similar circumstances. Thermal conductivity is measured by the amount of heat conducted by a unit volume of a substance, in a certain time, for a given driving force or difference in temperature between the opposite surfaces of the piece. In general, metals conduct heat much faster than other substances, such as wood, paper, cloth, or air. The former are called **thermal conductors**, whereas the latter are termed **thermal insulators**.

Chapter 2 (Continued)

SOME FUNDAMENTAL PRINCIPLES OF CHEMISTRY AND PHYSICS

PART 2 — FUNDAMENTAL PRINCIPLES OF CHEMISTRY

SECTION 1

BRANCHES OF CHEMISTRY

Traditionally, the science of Chemistry embraces two great divisions—**Organic Chemistry** and **Inorganic Chemistry**. Organic Chemistry deals with the composition and properties of compounds of carbon with the other chemical elements, usually excepting carbon monoxide, carbon dioxide, cyanides, the carbides and the carbonates. Inorganic Chemistry includes the study of all other substances, including the excepted compounds containing carbon just mentioned. The same general principles and laws are applicable to the study of both Organic and Inorganic Chemistry; the chief distinction between these two divisions of chemical science only involves the classes of compounds with which they are concerned. Since most metallurgical processes involve inorganic compounds, this discussion will deal largely with Inorganic Chemistry.

Physical Chemistry is devoted to the quantitative study of relationships between the chemical and physical properties and the constitution of substances, and is

a powerful metallurgical tool. Two branches of Physical Chemistry pertinent to metallurgical processes are **Thermochemistry** and **Electrochemistry**. **Thermochemistry** deals with the changes of heat content accompanying chemical reactions; since heat is either evolved or absorbed in all chemical reactions, this branch of chemical science is of basic importance in metallurgy, and is closely related to the physical science of **Thermodynamics** which is devoted to the mechanical effects of heat. **Electrochemistry** covers the field of study of the relationships between electricity and chemical changes: chemical changes in cells or batteries produce electricity, passage of direct electric current through molten substances or solutions produce chemical changes. Aluminum made by electrochemical processes, tin electrolytically deposited on steel to make electrolytic tin plate, and copper refined by electrolysis to a high degree of purity, are three examples of the importance of electrochemistry in metallurgy.

SECTION 2

CHEMICAL FORMULAS AND REACTIONS

Chemical Formulas of Compounds—The method of representing the elements by symbols, together with the system of atomic weights, affords a convenient and concise method of representing chemical compounds, or to be more explicit, the molecules of chemical compounds. Thus, by analysis, water is found to be composed of hydrogen and oxygen in the proportion of eight parts of oxygen to one part of hydrogen by weight. These facts are completely expressed by the formula H_2O , which indicates a molecule of a compound composed of two atoms of hydrogen and one atom of oxygen, or, since the atomic weight of hydrogen is 1 and oxygen 16, 2 parts of hydrogen to 16 parts of oxygen (1 to 8). Likewise, the formula Fe_2O_3 represents a compound, the molecule of which is made up of 111.70 parts of iron to 48 parts of oxygen.

Molecules of Elements—In studying chemical changes in which elements are set free, it is found that they are much more active at the instant of their liberation than afterwards. This fact leads to the belief that the instant

an element is set free from its compounds it exists in the atomic condition, but if there is nothing else present with which the atoms can combine, they combine with each other to form **molecules** of the element. This idea cannot be proved in the case of solids, but its correctness is easily shown in the case of gases. From many facts, Avogadro was able to show that **equal volumes of all gases, under standard conditions of temperature and pressure, contain the same number of molecules**. Hence, the molecular weight in grams of all gases occupies a constant volume of 22.4 liters, called the **gram-molecular volume**. Now, the weight of 22.4 liters of oxygen equals 32 grams; of hydrogen, 2 grams; of nitrogen, 28 grams. Dividing these weights by the respective atomic weights of the elements, the quotient is 2 in each case. Hence, the molecules of these elements contain two atoms each, and the correct formulas for these elements are O_2 , H_2 , and N_2 , respectively. Helium and some other elements do not have this tendency to unite into groups; in these elements, atom and molecule are iden-

tical. **Molecules**, therefore, are defined as the smallest particles of a substance that retain the characteristics of that substance.

Chemical Equations—This system of symbols and weights also simplifies the representation of chemical changes. Suppose it is desired to represent the chemical change that takes place when a common substance, like coal, burns. Coal is largely made up of carbon; the element which combines with carbon during the burning (combustion) of coal is oxygen in the air. An invisible gas, carbon dioxide (CO_2), is formed and diffuses into the air. This change, spoken of as a reaction, is represented in the form of an equation. Since matter is conserved, there must be as many atoms on one side of the equation as on the other. This is shown by placing a 2 before O on the left side of the equation, thus, $\text{C} + 2\text{O} = \text{CO}_2$. This process is called balancing. Thus, chemical equations tell not only the formulas of the reacting substances and of the products formed, but also give the proportions involved by weight, and in the case of gases, volume relations as well, if the reaction is balanced in molecules. Thus, $\text{C} + \text{O}_2 = \text{CO}_2$ indicates one volume of oxygen unites with C to form one volume of CO_2 . It will be observed in the latter form of the formula that the two atoms of oxygen involved in this reaction are expressed as O_2 instead of 2O as in the first form. As mentioned above under "Molecules of Elements," oxygen exists naturally as molecules consisting of two atoms. The molecular formula for oxygen (and other substances whose molecular formulas are known) is always used in writing equations to express this fact.

In writing chemical equations, considerable knowledge of a specific character is essential. First, it is necessary to know under what conditions the substances are brought together in order to tell whether or not they will react. If they do react, then the products formed and the formulas of all these substances must be known. As an example, consider the reaction of iron (hot) with water (steam) to form ferrosferric oxide and hydrogen. This knowledge can then be indicated thus: $\text{Fe} + \text{H}_2\text{O} = \text{Fe}_3\text{O}_4 + \text{H}_2$. The equation must be balanced, since the same number of atoms must be on both sides of the equality sign. This can be done by inspection. Finally, the reaction is reversible, for if instead of steam over hot iron, hydrogen be passed over hot iron oxide, iron and water are the products. The reaction is, therefore, correctly written thus: $\text{Fe}_3\text{O}_4 + 4\text{H}_2 \rightleftharpoons 3\text{Fe} + 4\text{H}_2\text{O}$, or $3\text{Fe} + 4\text{H}_2\text{O} \rightleftharpoons \text{Fe}_3\text{O}_4 + 4\text{H}_2$. Many reversible reactions, under conditions which do not permit the products to escape from the field of action, do not proceed to completion, but reach a balanced condition after a time and seem to stop, though as a matter of fact they are progressing in one direction as rapidly as in the other, hence are described as being in dynamic equilibrium.

The rate at which any reaction takes place depends on temperature, pressure or concentration, and the effect of any catalyst present. A catalyst changes the rate of reaction without itself being altered.

Heat of Reaction—The heat of reaction is the quantity of heat absorbed or liberated in a chemical change. Its value depends on the physical state of the reacting materials and products as well as the temperature. It is usual to give the standard heat of reaction which is defined as the change in heat content resulting from the reaction under a pressure of one atmosphere, starting and ending with all materials at a temperature of 18°C or 64.4°F .

Heat of formation represents a special case of the heat of reaction. The reacting materials are the necessary elements and the compound in question is the only product formed. Tables of the heat of formation of com-

pounds will be found in the standard texts on thermochemistry. By combining the heats of formation of various compounds, it is possible to calculate the heat of reaction for any reaction. The heat of formation of elements is zero. The heat of reaction is the difference between the sum of the heats of formation of the products and the sum of the heats of formation of the reactants.

The correction of the standard heat of reaction to the heat of reaction at some other temperature is necessary in actual practice, since few reactions take place at exactly 64.4°F . The calculation is based on a consideration of the initial and final states of any system. The same net amount of heat is required to go from some initial state to some final state regardless of the path or method used in making the change. If this were not true we would go by the path requiring the least heat and come back by the path requiring the most heat. This would give us a net amount of heat, and we would have a source of heat without doing any work or a kind of perpetual motion.

To make the correction, the amount of heat required to raise the reacting materials and products from 64.4°F to the temperature of reaction are calculated from the heat capacities, and any heats of change of state and transformation. Now the standard heat of reaction plus the heat added to the products is equal to the heat added to the reacting materials plus the heat of reaction at the desired temperature.

Kinds of Reactions—As already indicated, all reactions may be placed under one of two heads; namely, those that liberate heat, called exothermic, and those that absorb heat, called endothermic. A more detailed classification, such as the following, is sometimes employed:

1. Direct combination: $2\text{H}_2 + \text{O}_2 = 2\text{H}_2\text{O}$.
2. Direct decomposition: $2\text{HgO} = 2\text{Hg} + \text{O}_2$.
3. Simple replacement or substitution:
 $2\text{H}_2\text{O} + 2\text{Na} = 2\text{NaOH} + \text{H}_2$.
4. Double replacement:
 $\text{BaCl}_2 + \text{H}_2\text{SO}_4 = \text{BaSO}_4 + 2\text{HCl}$.
5. Oxidation— $\begin{cases} 3\text{Fe} + 2\text{O}_2 = \text{Fe}_3\text{O}_4 \\ 2\text{FeCl}_2 + \text{Cl}_2 = 2\text{FeCl}_3 \end{cases}$.
6. Reduction— $\begin{cases} \text{Fe}_3\text{O}_4 + 4\text{H}_2 = 3\text{Fe} + 4\text{H}_2\text{O} \\ 2\text{FeCl}_3 + \text{H}_2 = 2\text{FeCl}_2 + 2\text{HCl} \end{cases}$.

The two processes of oxidation and reduction are of great importance in metallurgy. They have a triple meaning. Primarily, oxidation means the taking on of oxygen by an element or compound, and reduction means the giving up of oxygen. In the case of elements that form more than one compound, if the number of atoms of one that combines with a fixed number of the other be increased, the process is oxidation; if decreased, reduction. In metallurgy an element in the metallic state is said to be reduced. The two processes are inseparable; when one thing is reduced, another is oxidized. In metallurgical operations these two processes are of paramount importance, for all the substances reduced constitute the metallic product and all in oxidized form make up the slag.

SECTION 3

KINDS OF CHEMICAL COMPOUNDS

A close study of a great number of chemical compounds shows that these substances fall into four classes; namely, acids, bases, salts, and nonelectrolytes.

Acids are characterized by the fact that they all have a sour taste when in water solution and change the color of certain chemicals, called indicators. A common indicator is litmus, the color of which is red in the presence of acids.

Bases have the power of neutralizing acids, and may be looked upon as their opposites. Examples are quicklime, lye, etc. Bases change the color of red or neutral litmus to blue.

Salts are the products formed when acids are neutralized by bases. Common table salt, made by neutralizing hydrochloric acid with sodium hydroxide, is an example. As a rule acids, bases, and salts are electrolytes, that is, their water solutions will conduct the electric current.

Nonelectrolytes—There are some compounds that do not resemble either acids or bases, nor can they be classed as salts. They are characterized by the fact that their water solutions will not conduct the electric current, so are termed nonelectrolytes. Ordinary sugar is an example.

Anhydrides—Inorganic acids and bases, in general, can be decomposed by heat. Acids and bases are broken up into water and oxides, the oxides being called anhydrides. Acids give acid anhydrides, and bases, basic anhydrides. These anhydrides, at elevated temperatures, have the same power of neutralization that their corresponding compounds possess in water solution. Thus,

acid and basic anhydrides can react to form neutral compounds to which the term **slag** is applied instead of salt. Many salts, in crystallizing from aqueous solutions, unite with or, better, take up a definite amount of water, which does not go to form a new compound, but to form crystals, and is called, therefore, **water of crystallization**. This water is held very loosely by the molecule and is readily given up by it. In some crystals, like those of washing soda, for example, this tendency is so pronounced that they give up their water of crystallization to the air, if its humidity is low. Such substances are said to be **efflorescent**. On the other hand, many dry substances absorb moisture from the air and are, therefore, said to be **hygroscopic**. A few substances will absorb enough water from very moist air to become wet and actually go into solution in the water they absorb. These substances are said to be **deliquescent**. The following reactions will serve to illustrate these facts insofar as they involve chemical changes:

SECTION 4

VALENCE AND VALENCE NUMBERS

Valence—Reference was made in Section 3 of Part 1 of this chapter, under "The Electronic System," to the designation as **valence electrons** of the electrons in the two outermost "shells" or energy levels of the electronic system of the atom. In some chemical changes, an actual transfer of electrons from an atom of one element to an atom of another element takes place. An atom or group of atoms that loses electrons becomes positively charged; any that gain electrons become negatively charged, since the normally electrically neutral state of the atom is unbalanced by the gain or loss of negatively charged electrons. Two atoms that have become oppositely charged may become bound together by these electrical charges of opposite sign that result from an actual transfer of electrons. What are called **ionic substances** are formed in this manner.

Atoms of two (or more) elements involved in a chemical change may, instead of having electrons actually transferred between atoms, share electrons; the shared electrons then link the atoms together to form molecules.

In the case of ionic substances, the charge on an element in a given compound is the **ionic valence** of that element, and is either positive or negative as described for the case of the sodium ions (Na^+) and sulphate radical ions (SO_4^{--}) mentioned later in the discussion of "Ions and Electrolysis."

When molecules of a substance are formed by two

Fig. 2-7. Schematic representation of covalence in which molecules are formed by atoms sharing electrons. These are special cases of non-ionic valence.

atoms sharing electrons, the atoms are said to have **non-ionic valence**. Figures 2—7a and 2—7b show special cases of non-ionic valence, where molecules are formed by atoms sharing pairs of electrons in which each electron of a pair is spinning in an opposite direction; this is termed covalence which, unlike ionic valence, is neither positive nor negative.

Valence Numbers—In balancing chemical equations, as will be discussed later, the **valence number** representing the **apparent valence** of an element is a useful aid. To determine valence numbers of the atoms in a compound, it is customary to arbitrarily consider each hydrogen atom as having a unit positive charge and each oxygen atom as having a double negative charge. The valence numbers of any other atoms in the compound are then calculated to be either positive or negative and of such magnitude that the algebraic sum of the valence numbers of all the atoms in the compound is zero. For

example, in sulphuric acid (H_2SO_4), the two hydrogen atoms would have a total charge of $2 \times (+1)$ or $+2$, and the four oxygen atoms a total charge of $4 \times (-2)$ or -8 ; the sulphur atom then would have a valence number of $+6$ if the numerical sums of the charges of opposite sign are to be equal. It should be stressed that a valence number of $+6$, as in this case, does not mean that the sulphur atom actually has lost six electrons to acquire a positive charge of $+6$; in other words, valence numbers are for convenience in chemical calculations, and do not necessarily represent **true valence**. Valence numbers indicate the **valence state** of an element in a particular compound. In the case of sulphur in sulphuric acid just mentioned, the valence state of the sulphur would be indicated by S^6 , which is called a **valence state symbol**. Atoms with valences of one, two, three, etc., respectively, are said to be univalent, divalent, trivalent, etc.

SECTION 5

RADICALS

In the molecules of many chemical compounds, certain groups of atoms appear to be more closely bound together than others in the same molecule. In these groups the atoms composing them appear to bear a fixed relation to each other, which remains unchanged during a chemical reaction. Thus, in many wet reactions in which H_2SO_4 is employed as a reagent, the sulphur and oxygen do not separate but remain closely combined, as illustrated in the reaction that takes place between this acid and barium chloride to form barium sulphate and hydrochloric acid:

Such a group of atoms, as typified by (SO_4) above, is called a **radical**. Thus, a radical may be defined as a group of atoms which are combined chemically in such a way that they act as an atom of a single element. Among the more commonly encountered radicals are the sulphate radical just mentioned (SO_4), the nitrate radical (NO_3), the phosphate radical (PO_4), the hydroxyl radical (OH) and the ammonium radical (NH_4).

SECTION 6

IONS AND ELECTROLYSIS

Distilled water, that is, water which contains no dissolved chemicals, has a very high resistance to the flow of electric current. However, when a substance like sodium chloride is dissolved in distilled water, the resulting solution will readily conduct a current. The reason is that the sodium chloride dissociates into electrically charged units, or parts of the molecule, called **ions**. It is these ions which are conducting the current.

FIG. 2—8. Decomposition of water and formation of sodium hydroxide and sulphuric acid from sodium sulphate by electrolysis.

The following simple experiment may be employed to throw additional light upon this subject. Into the U-tube of Figure 2—8 is placed a solution of sodium sulphate and some neutral litmus, into which are immersed two small platinum rods to act as electrodes for an electric current. Upon closing the circuit, bubbles of hydrogen are given off at the cathode or negative pole and bubbles of oxygen at the anode or positive pole, while the solution about the cathode becomes deep blue in color, showing it is basic, and that about the anode becomes red, showing it to be acid. These facts are explained by assuming that the molecules of dissolved Na_2SO_4 dissociate into parts called ions. This dissociation is indicated thus: $\text{Na}_2\text{SO}_4 = \text{Na}^+ + \text{Na}^+ + \text{SO}_4^{--}$. The sodium ions, Na^+ , carrying a positive charge of electricity, are propelled by the current toward the cathode (the negative pole), while the negatively charged sulphate ions, SO_4^{--} , each carrying a double negative charge, go to the anode or positive pole. Here they give up their charges and become chemically active, decomposing the water thus:

Hydrogen and oxygen are the products. It is the basic sodium hydroxide (NaOH) which causes the solution at the cathode to become blue, and the sulphuric acid (H_2SO_4) which causes the solution at the anode to turn

red. However, if the portions of solution were brought together by stirring, the hydroxide and acid would react to reproduce once more the original sodium sulphate. This experiment is but one example of electrolysis. Any inorganic acid, base, or salt may be substituted for the sodium sulphate; and any conductor of electricity may be used instead of platinum.

It has been found that one gram equivalent weight of matter, that is the atomic weight in grams divided by the valence, is chemically altered at each electrode for each 96,500 coulombs, or one faraday, of electricity passed through the electrolyte. This is known as Faraday's Law. A coulomb is an amount of current equal to the flow of one ampere for one second.

SECTION 7

FUNDAMENTAL LAWS OF CHEMICAL CHANGE

Law of Constancy of Nature—Under the same conditions, reactions involving the same substances will always produce the same results.

Law of Conservation of Matter—Early in the history of science, a most fundamental conclusion was reached; namely, that matter can neither be created nor destroyed; in other words, the amount of matter in the universe cannot be increased or decreased. Thus, in every chemical process, the quantity of matter remains constant and only the form changes; that is, the total mass of substances which react chemically is equal to the mass of the resulting products. In recent years, nuclear physicists working on the splitting of atoms (nuclear fission) have discovered that actually matter can be converted into energy, so that strictly speaking this law is not entirely valid and must be amended. However, this matter need not be considered here, since for ordinary chemical and physical processes the law holds accurately.

The Law of Definite Proportions (Dalton's first law) states that when elements combine to form a substance, they do so (with a few exceptions) in definite proportions by weight. For example, 112 parts by weight of iron will combine with 48 parts by weight of oxygen to form Fe_2O_3 , or fourteen parts by weight of nitrogen will combine with sixteen parts by weight of oxygen to form nitric oxide (NO). The definite weights are called combining weights.

Some pairs of elements form more than one compound, and the combining weights of the elements in these compounds are simple multiples of each other. This fact is stated in the **Law of Multiple Proportions** (Dalton's second law) as follows: when two elements unite to form more than one compound, if a fixed weight of the one is considered, the weights of the other which combine with it are integral multiples of one another. The following compounds are examples:

Compound	Parts by Weight Nitrogen	Parts by Weight Oxygen
Nitrous oxide, N_2O	28	16
Nitric oxide, N_2O_3 or NO	28	32
Nitrogen trioxide, N_2O_5	28	48
Nitrogen peroxide, N_2O_4 or NO_2	28	64
Nitrogen pentoxide, N_2O_5	28	80

Since atoms do not subdivide in chemical changes, it is easy to see that the foregoing two laws must be true, since whole numbers of one type of atom will always combine with whole numbers of other atoms. Since atomic weights are fixed, the combining weights would have to be simple multiples related to the numbers of atoms involved.

Qualitative Considerations—In practical chemical work it is usually desirable to have reactions go to an end. Hence it is desirable to have in mind two laws of equilibrium. According to **Le Chatelier's Law**, the application of a stress, i.e., change of temperature, concentration, or pressure, to a system in equilibrium causes a reaction, displacing the equilibrium in the direction that tends to undo the effect of the stress.

A particular case of this law is van't Hoff's law of mobile equilibrium which states that if the temperature of a system in equilibrium is raised, the equilibrium point is displaced in the direction that absorbs heat. This law applies to both chemical and physical equilibria.

As an aid in writing reactions the following laws may be found of value:

- A. The reaction of two or more substances will go to an end, that is, will be complete, provided:
 - (1) One of the products is volatile at the temperature of the reaction.
 - (2) One of the products is insoluble in the solvent in which the reaction takes place.
 - (3) One of the products is a nonelectrolyte, that is, does not ionize in the solvent.
- B. The speed of a chemical action in a given direction may be increased by effecting a greater concentration of one of the reacting substances. This is a simple, nonmathematical statement of the law of mass action.
- C. Chemical reactions always tend to proceed in the direction that will liberate the most heat, and without the addition of heat from an external source those substances that have the greatest heats of formation will tend to form.

SECTION 8

SOLUTIONS

There are no good rules to predict the extent to which a substance will dissolve in a liquid. In dilute solutions the component present in large excess is called the solvent, and the dissolved substance is called the solute. The concentration of the solute may be expressed in mol fractions. The mol fraction of a solute in a solution is the number of molecular weights of the solute present, divided by the number of molecular weights, or mols,

of all substances present. An example of calculating mol fraction will be found in the section of this chapter on chemical calculations. The sum of the mol fractions of the various components in a solution must be one.

Distribution Coefficient—If two liquids are insoluble in each other and a third component, the solute, is added, the solute will distribute itself between the two immiscible layers in such a way as to satisfy its solu-

bility in the two liquids as well as its ability to react with either or both of the liquids. The ratio of its concentrations in the two layers is called the **distribution coefficient**. The distribution coefficient is a constant for each pair of mutually insoluble liquids with a particular solute. The constant changes with temperature. It is a constant regardless of the amount of solute or relative quantities of the two immiscible solvents.

Vapor Pressure of Solutions—Several rules have been developed for calculating the vapor pressure of solutions. One is **Raoult's Law** for the solvent. This states that the partial vapor pressure of the solvent in equilibrium with a solution is directly proportional to its mol fraction. That is, the partial vapor pressure exerted by the solvent is equal to the vapor pressure of the pure solvent at the temperature in question times the mol fraction of solvent present. If the solute is non-volatile the partial vapor pressure of the solvent is the total vapor pressure. **Henry's Law** states that the partial vapor pressure due to a volatile solute is proportional to its mol fraction. The value of the proportionality constant for Henry's Law must be determined experimentally for each system and at each temperature.

Phase or Constitution Diagrams—Many metals are soluble in each other (at least partially) in the liquid state, and some remain dissolved in each other in the solid state after their liquid solution has cooled sufficiently to change from the liquid to the solid state. As a special part of the study of solutions, a knowledge of the changes in metals and alloys with variation in chemical composition and with mechanical and thermal treatments can be expressed by phase or composition diagrams, which, however, refer only to systems that are in equilibrium. A large number of these diagrams covering most of the binary alloys and many multi-component alloys have been determined experimentally. These have become the basis for deciding compositions and heat treatments to give the desired properties for a particular application. These diagrams, also called **phase, equilibrium composition or constitution diagrams**, are widely used in the refractory field.

The phases of a system are the parts which are separated from one another by definite physical boundaries. For example, a liquid in contact with a solid has a definite physical boundary, thus two phases, a liquid and a solid, are present. Also, since every solid phase is characterized by a distinctive atomic configuration, a discontinuous change in type or spacing of atom packing is necessarily a phase change. Two mutually insoluble

materials, whether as liquids or as solids, show two phases.

Time-Temperature Curves—One method that can be used to determine the phase diagram is to heat a mixture until it melts and then to plot the change in temperature with time as the mixture cools with a constant outside temperature environment. The shape of time-temperature curve obtained will depend on the heat loss of the system and the energy changes occurring within the system. As long as only liquid is present, cooling (temperature-drop versus time) will proceed at a gradually decreasing rate, and the time-temperature relationship will be a continuous curve. However, whenever material is crystallized, or solidified, the heat of fusion is liberated, and this liberation of the heat of fusion within the material furnishes the heat that is being lost from the system, causing the temperature to remain fairly constant. This results in a leveling or "jog" in the time-temperature curve. Whenever all the material has solidified the temperature will again drop, and the time-temperature curve will again become continuous.

If, during the cooling of the solid to room temperature, there is a crystal change or the formation of an additional phase because of mutual solubility decrease, the heat of transformation will be liberated and another jog in the time-temperature curve will be noted. Some of these changes are accompanied by such a small liberation of heat, or at such a slow rate, that the effects on the time-temperature curve are slight and other methods, such as micrographic analysis, X-ray diffraction, dilatometric measurements, etc., must be used to find the temperature where the change to another phase takes place.

After obtaining the time-temperature curves for a number of compositions, phase diagrams can be constructed by plotting the temperature where jogs appear in the time-temperature curves as a function of the composition of the alloy being studied. A study of the freezing of solutions has shown that they fall into two classes: (1) those in which the ingredients in solution in the liquid state remain in solution in the solid state, and (2) those in which the state of solution is not maintained in the solid state, that is, those in which the ingredients separate on freezing. Both classes are encountered in the study of alloys.

An Example of the First Class of Solutions—One of the best examples of the first kind of solution is a mixture of gold and silver. If quantities of these two metals

FIG. 2-9. Diagram of the freezing of liquid gold-silver alloys.

be placed in a vessel and heated until they melt, a homogeneous mixture, or a liquid solution, results; and if this mixture be allowed to cool to the solid state, it remains homogeneous, that is, it is a solid solution. A study of many mixtures in which the proportions of gold to silver are varied shows that freezing begins and ends at a different temperature for each mixture. Pure gold freezes at 1444° F (1949° F according to some authorities) and pure silver at 1762° F, and the freezing points of mixtures occur between these two points. Unlike the pure metals, however, these mixtures do not solidify completely at a constant temperature, but their freezing is prolonged through ranges of temperature. These facts, determined definitely by experiment, may be represented by a diagram, or curve, in which the ordinates represent temperatures and the abscissae the percentage of gold or silver or both.

A typical time-temperature curve for this system is shown in Figure 2—9, to the left of the diagram. Point "F" shows the temperature where freezing starts and point "S" is the temperature where freezing ends and below which only solid is present.

To illustrate further, suppose 60 oz. of gold be mixed with 40 oz. of silver, and the whole heated to a temperature of 1994° F. The locus of this point would be at "L" in the region of the liquid state. If now, this molten solution be allowed to cool slowly, crystallization will begin at "F," about 1906° F, and end at "S," about 1814° F. The first crystals formed will be richer in gold than the liquid—the proportion being, in this case, about 90 parts gold to 10 parts silver—while the crystals formed last will be richer in silver than the mother liquid; but the average composition of all will be the same, namely 60 per cent gold and 40 per cent silver. Furthermore, while solidification is going on, a process of diffusion takes place and tends to adjust the composition of each individual crystal, thus bringing it nearer that of the average. Therefore, under normal (non-equilibrium) cooling conditions, each crystal exhibits a continuous variation in composition from the center, which would be the first to freeze, to the outside which would be the last to freeze.

An Example of the Second Class of Solutions—The second class of solutions exhibits complete solubility in the liquid state and only partial solubility in the solid state. An example is the silver-copper series of alloys, the phase diagram of which is shown in Figure 2—10.

The 5 per cent copper—95 per cent silver alloy in this series is typical of alloys containing up to 8.5 per cent

copper, and is indicated as point "N" on the phase diagram. Suppose this alloy be heated to a temperature of 2000° F. As this temperature is above the fusion points of silver and copper, it is sufficiently high to insure that the mixture will be completely liquefied. On cooling this solution, no crystallization takes place until a temperature of about T_1 is reached, at which temperature, crystals of alpha phase (silver in which is dissolved a small amount of copper) begin to separate from the solution, making the remaining solution poorer in silver but richer in copper. The separation of the alpha phase causes a retardation of the rate of cooling, showing that heat is evolved thereby; and the freezing point of the mother liquid is lowered, so that no further separation of alpha phase takes place until more heat is abstracted. This retardation in the rate of cooling is reflected by a distinct change of slope in the time-temperature cooling curve. If the cooling be continued, however, the separation of the alpha phase will also continue. From the time-temperature cooling curves of alloys of different compositions, the points at which freezing starts; i.e., the points at which the slope of the curve changes, are plotted to give the line "MO" shown in Figure 2—10.

When the cooling with the accompanying separation of alpha has reached the temperature T_2 , all of the liquid has frozen to the alpha phase which has an average composition of 95 per cent silver and 5 per cent copper. The temperature at which freezing ends is reflected by another change in the slope of the time-temperature cooling curve and, from cooling curves of alloys of different composition, the temperatures at which this change of slope occurs are plotted against the composition of the alloy (line "MN" on the diagram).

On further cooling, nothing happens until the temperature T_3 is reached. At this temperature, small crystals of the beta phase (copper, in which is dissolved a small amount of silver) begin to separate from the solid alpha phase and this separation continues as the temperature decreases. Therefore, at room temperature, the equilibrium structure of the 5 per cent copper—95 per cent silver alloy consists of primary crystals of the alpha phase in which are dispersed, often in a geometrical pattern, smaller crystals of the beta phase.

The line "NP" on the phase diagram gives, for any particular alloy, the temperature at which the beta phase begins to separate from the alpha phase and thus shows how the solubility of the copper in the alpha phase is affected by temperature. The points for this line are usually determined by X-ray diffraction.

The behavior of alloys having compositions between points "N" and "O" on the phase diagram can be described by considering an alloy containing 20 per cent copper and 80 per cent silver. This alloy begins to freeze at a temperature of T_4 and the freezing proceeds in a manner similar to that described for the 5 per cent copper—95 per cent silver alloy. However, when the temperature of T_5 is reached, part of the alloy is still liquid and the composition of the remaining liquid, designated by the point "O," is called the eutectic composition. At this temperature, called the eutectic temperature, the remaining liquid freezes into minute crystals of alpha and beta phase.

The heat liberated by the simultaneous freezing of the alpha and beta phases causes a distinct jog in the time-temperature cooling curve similar to that which occurs when a pure metal freezes. Thus, when cooling an alloy having a composition corresponding to the eutectic composition, the time-temperature cooling curve is the same as that obtained when a pure metal freezes.

Alloys whose compositions lie to the right of the eutectic composition freeze in a manner similar to that

FIG. 2—10. An example of second class of solutions. Freezing of liquid silver-copper.

described above except that for the alloys to the right the beta phase is the first to separate.

Ternary Systems—As the number of components in a system increases, the graphical presentation of equilibrium conditions in that system becomes more difficult. With a three component system, a three-dimensional diagram is required to show all compositions within the system. Each apex of the equilateral triangle forming the base of the three dimensional diagram represents 100 per cent of one of the components, and any point within the triangle must always add up to 100 per cent, simple geometric relationships determining the percentage of each component present. With the diagram thus devoted to composition, there remains the problem of representing the other variables of pressure and temperature. Accordingly, pressure is held constant, usually at one atmosphere, as with binary systems, while tem-

perature is represented by an ordinate projecting upward at right angles from the base composition triangle. Thus, with most ternary diagrams, the reader is really looking at the uneven top surface of a triangular prism whose height at any point on that surface represents the liquidus temperature for that composition. However, temperatures are usually projected onto the base composition triangle where they appear as isotherms, together with the boundary lines of phases in equilibrium at the liquidus temperatures.

While the foregoing is sufficient to provide considerable useful information concerning a ternary system, the ability to follow the devious paths of melting or crystallization and to determine the shifting compositions and percentages of liquids and solids along these paths requires a far more intimate knowledge of phase-rule application than can be provided here.

SECTION 9

CHEMICAL NOMENCLATURE

General Principle—The names of the elements first discovered, and, therefore, unfortunately, the more common ones, are not based on any principle; but of the more recently discovered elements the metals have received names ending in *um* or *ium*, and the metalloids, in *n* or *ne*. In the naming of compounds, however, the old names have been discarded and new ones substituted. The system employed in assigning these new names is this: The name of a compound should show the elements of which it is composed, and as far as possible their relative proportions.

Terminology of Binary Compounds—The simplest compounds are those composed of only two elements. The names of all such compounds are made up of the name of the basic element, if one is present, succeeded by the name of the acid element, which ends in *ide*. Examples: ferrous (iron) sulphide, (FeS); sodium chloride, (NaCl); calcium oxide, (CaO).

In such cases as iron and sulphur, where the same two elements combine to form more than one compound, the compounds, when two in number, are distinguished by changing the ending of the metallic part of the name from *ous* to *ic*; thus, ferrous sulphide, (FeS); ferric sulphide, (Fe₂S₃); stannous chloride, (SnCl₂); stannic chloride, (SnCl₄). In the compounds for which the metallic element is given the *-ic* ending, the apparent valence of the metal is more positive than that of the metal in the *-ous* compounds. For example, the apparent valence of iron atoms in ferrous compounds is +2; in ferric compounds, +3. Often a prefix is added to the name of the acid element to indicate the number of its atoms to the molecule. Carbon dioxide (CO₂) and carbon monoxide (CO) are examples. When radicals are present in a compound, the compound contains the name of the radical unchanged. Zinc nitrate, Zn(NO₃)₂, and ammonium sulphate, (NH₄)₂(SO₄) are examples.

Terminology of Ternary Compounds—The names of compounds that contain three elements, provided they are not derived from acids, may end in *ide*. In this case all three of the elements appear in the name, as sodium aluminum fluoride, (Na₃AlF₆), bismuth oxychloride, (BiOCl). A few ternary compounds derived from *ic* acids have names ending in *ate*, as potassium chlorplatinate, (K₂PtCl₆).

Terminology of Acids—Acids are composed of the acid-forming elements in combination with hydrogen or with hydrogen and oxygen. The name of a given acid is derived from the name of the acid-forming element and may end in *ic*. An example is hydrochloric acid (HCl).

Acids, like sulphuric (H₂SO₄) and orthophosphoric (H₃PO₄), which contain more than one replaceable hydrogen atom are called, as a class, **polybasic acids**; and in individual cases, the different acids are referred to as **di**basic or **tri**basic. For example, potassium and sodium may replace the two hydrogen atoms in H₂SO₄ to form sodium potassium sulphate (NaKSO₄). In all such double salts, both the base-forming elements must appear in the name of the salt.

Terminology of Bases—The base-forming elements form compounds with hydrogen and oxygen in which these two elements appear as a group, OH, called the **hydroxyl radical**. Hence, these compounds are called **hydroxides**. Sodium hydroxide, NaOH, is an example.

Terminology of Salts—Salts take their names from those of the base-forming elements and the acids of which they are composed, changing the endings of the acids. Salts of acids that end in *ic* change this ending to *ide* and *ate*, and those that end in *ous*, to *ite*. Thus, sodium chloride, (NaCl), derived from hydrochloric acid, sodium perchlorate, (NaClO₄), from perchloric acid, and sodium chlorite, (NaClO₂), from chlorous acid, are examples. Other systems of nomenclature are in use, but the ones just noted cover the largest field.

Neutralization—Hydroxyl and Hydrogen Ions—When an acid is mixed with water, dissociation of the molecules takes place and ions are formed which carry positive and negative charges. The positive ions are hydrogen and the negative ions are the acid radicals. When a base dissolves, a similar dissociation of the molecules takes place, the positive ion being the metal and the negative, the group OH, called **hydroxyl ions**. If the solutions of an acid and a base are mixed, a salt is formed from the union of the metal with the acid radical and water is formed from the union of the hydrogen ions with the hydroxyl ions. These changes may be illustrated with hydrochloric acid and sodium hydroxide in solution, and written thus:

From this it will be seen that, chemically defined, an acid is a compound which in solution gives hydrogen ions, while a base gives hydroxyl ions, and the fundamental neutralization reaction is the simple expression, $\text{H}^+ + \text{OH}^- \rightarrow \text{H}_2\text{O}$.

SECTION 10

CHEMICAL CALCULATIONS

Kinds of Problems—Chemical calculations are of great importance because they make it possible for the operator to predict the quantity of material needed for certain chemical and metallurgical reactions. In the case of solids (iron ore, limestone, etc.) the calculations are generally made in terms of weight. In the case of gases (oxygen, carbon dioxide, etc.) the calculations could also properly be made in terms of weight, but it is more convenient to think in terms of volumes, and, since the relation between weight and volume (of gases) is known, many gas calculations are carried out in terms of volumes.

The calculations are possible because chemical elements (such as carbon or oxygen) or compounds (such as carbon monoxide or calcium oxide) always combine with other elements or compounds in definite proportions. For example in the well-known metallurgical reaction in which oxygen (O) combines with carbon (C) to form carbon monoxide (CO), it will always happen that 16 grams of oxygen will combine with just 12 grams of carbon (neither more nor less) to form 28 grams of carbon monoxide. Similarly, when carbon monoxide (CO) gas is burned by reaction with oxygen to form carbon dioxide (CO₂) gas, it will always happen that 16 grams of oxygen will combine with 28 grams of CO to form 44 grams of CO₂. Sixteen grams of oxygen will never require 27 or 29 or 30 grams of CO, but always just 28 grams of CO to make CO₂.

The reason for the foregoing is the fact that one atom of oxygen always combines with just one atom of carbon in the first reaction above, and one atom of oxygen weighs 16 units and one atom of carbon weighs 12 units on the atomic scale.

These circumstances have resulted in a kind of chemical shorthand, in which the first reaction above is written as follows:

To the chemist, this says at once that the elements carbon and oxygen react here in the ratio of one atom of carbon to one atom of oxygen, and since the chemist knows that oxygen has an atomic weight of 16 and carbon has an atomic weight of 12, he knows that 16 units of oxygen will always react with 12 units of carbon, by weight. (The expression " $\frac{1}{2}\text{O}_2$ " is used in the equation to represent one atom of oxygen in recognition of the fact that oxygen normally exists in the molecular state, with two atoms in each molecule.)

A combination of atoms is called a molecule. Thus CO is a molecule. Its weight is called the molecular weight and is equal to the sum of the weights of the atoms of which it is composed. CO is called the formula of carbon monoxide.

The principles of calculation, using round numbers for atomic weights in some instances, are illustrated in the following simple examples.

Four Problems Involving Weight

(1) **Calculation of molecular weight from the chemical formula, the separate atomic weights being known.** This is a simple arithmetical addition. Suppose the formula of copper sulphate is known to be CuSO₄, and suppose the atomic weights are known to be as follows:

Copper (Cu)	atomic weight 63.54
Sulphur (S)	atomic weight 32.06
Oxygen (O)	atomic weight 16.00

Then the molecular weight of copper sulphate CuSO₄ must be:

1 Copper	63.54 × 1 = 63.54
1 Sulphur	32.06 × 1 = 32.06
4 Oxygen	16.00 × 4 = 64.00
Sum	= 159.60

The molecular weight of copper sulphate, CuSO₄, is thus 159.60.

(2) **Calculation of percent by weight of each element in a compound, the atomic weights being known.** Using the data of Problem No. 1 just above, it is recognized that the weight of the copper, Cu, is 63.54 and the weight of the copper sulphate, CuSO₄, is 159.60. Consequently the copper constitutes

$$\frac{63.54}{159.60} \text{ or } 39.81\% \text{ by weight, of the copper sulphate.}$$

In the same way the sulphur constitutes

$$\frac{32.06}{159.60} \text{ or } 20.09\% \text{ by weight, of the copper sulphate.}$$

Likewise, the oxygen constitutes

$$\frac{64.00}{159.60} \text{ or } 40.10\% \text{ by weight, of the copper sulphate.}$$

The total of course adds up to

Copper	· 39.81%
Sulphur	· 20.09
Oxygen	· 40.10
Total	<u>100.00%</u>

(3) **Calculation of the Formula of a Compound, from its Chemical Composition.** A substance, known to be a chemical compound and known to be pure, is of the following composition:

Calcium, Ca	29.44% by weight
Sulphur, S	23.55% by weight
Oxygen, O	47.01% by weight
Total	<u>100.00%</u>

The problem is to find the molecular formula, the atomic weights of the three elements being known to be:

Calcium	40.08
Sulphur	32.066
Oxygen	16.00

It will be seen that this is just the reverse of problem 2, where it was desired to calculate, from the formula, the proportion (by weight) of each element, instead of the formula from the proportions by weight (as in this case).

In this case, a certain number of atoms of calcium, of atomic weight 40.08, make up 29.44% of the total weight. Then 29.44 divided by 40.08 is a number which is proportional to the number of atoms of calcium.

$$\frac{29.44}{40.08} = 0.7344 \text{ for Ca}$$

Similarly, 23.55 divided by 32.066 is a number which is proportional to the number of sulphur atoms.

$$\frac{23.55}{32.066} = 0.7344 \text{ for S}$$

Similarly, 47.01 divided by 16.00 is a number which is proportional to the number of oxygen atoms.

$$\frac{47.01}{16.00} = 2.938$$

The calcium, sulphur and oxygen atoms are thus present in the proportion

$$0.7344 \text{ to } 0.7344 \text{ to } 2.938$$

which is about the same as 1 to 1 to 4.

Consequently, the formula of the above compound would be written CaSO_4 , which means that each molecule of the compound contains one atom of calcium and one atom of sulphur and four atoms of oxygen, and is therefore the compound known as calcium sulphate.

(4) **Calculation of Relative Weights from the Chemical Equation.** Problem: Five per cent of a certain limestone is nonvolatile impurities and 95 per cent is pure calcium carbonate. What will be the weight of lime obtained from calcining 2000 lbs. of this stone?

Weight of impurities = 5% of 2000 = 100 lbs.

Weight of calcium carbonate = 1900 lbs.

Reaction on calcining ... $\text{CaCO}_3 + \text{heat} = \text{CaO} + \text{CO}_2$
Combining or atomic wts. $40 + 12 + (3 \times 16) =$
 $(40 + 16) + [12 + (2 \times 16)]$

Relative or molecular wts. $100 = 56 + 44$

Since 100 lbs. CaCO_3 give 56 lbs. CaO

1900 lbs. CaCO_3 give 1064 lbs. CaO

1064 lbs. CaO + 100 lbs. nonvolatile impurities =
1164 lbs. of burned product.

Problems Involving Volume Only

Calculation of Relative Volumes of Gases—Avogadro's hypothesis states that equal volumes of all gases at standard conditions of temperature and pressure, which are 32°F (0°C) and 29.92 in. (760 mm) of mercury barometric pressure, contain the same number of molecules. The weights of these equal volumes are proportional to the molecular weights of the gases. If the weights are expressed in grams, each gram-molecule of the gases involved represents 22.4 liters under standard conditions; if in pounds, each pound-molecule occupies 359 cubic feet. Problems involving volumes of gases only are, therefore, very simple to solve, because the relative volumes are identical with the coefficients of the molecules, as will be evident from an inspection of the following examples.

1 vol. hydrogen + 1 vol. chlorine gives 2 volumes hydrochloric acid gas.

1 vol. methane + 2 vol. oxygen gives 1 vol. carbon dioxide + 2 vol. water vapor.

Problems Involving Both Weight and Volume

Indirect Method—This method necessitates finding the relative weights of the gases involved from which the volumes may be calculated from the specific gravity, or the weight of a unit volume.

Problem: How many cubic feet of carbon dioxide measured under standard conditions would be given off by 2000 lbs. pure calcium carbonate during the process of calcination? (The weight of one cubic foot of carbon dioxide is 0.1225 pounds at standard conditions.)

Since 100 lbs. CaCO_3 give 44 lbs. CO_2
2000 lbs. CaCO_3 give 880 lbs. CO_2
 $880 \div 0.1225 = 7180 \text{ cu. ft.}$

Direct Method—The fact that molecular weights of gases occupy constant volumes at standard conditions affords a simple direct method for calculating volumes from the equation.

Since the molecular weight of CaCO_3 is 100, then one pound-molecule of CaCO_3 is equal to 100 pounds. From the equation it can be seen that one pound-molecule of CaCO_3 yields one pound-molecule of CO_2 . Since one pound-molecule of any gas is equal to 359 cubic feet at standard conditions:

100 lbs. CaCO_3 gives 359 cu. ft. of CO_2
2000 lbs. CaCO_3 gives 7180 cu. ft. of CO_2

Mol Fraction

Problem: Find the mol fraction of the solute (sulphuric acid) and solvent (water) in a solution containing 10% by weight sulphuric acid in water.

Number Moles = $\frac{\text{Pounds}}{\text{Molecular Weight}}$

Take as the basis 100 pounds of solution.

Chemical Formula	Lbs.	Mol. Wt.	No. Mols	Total No. Mols	Mol Fraction
H_2SO_4	10	98	0.102	5.102	0.02
H_2O	90	18	5.000	5.102	0.98
	100		5.102		1.00

SECTION 11

SOME ELEMENTS COMMON IN STEELMAKING

Oxygen

Atomic Number, 8. Atomic Weight, 16. Molecular Weight, 32. Valence, II. Specific Gravity: Hydrogen Standard, 15.896; Air Standard, 1.1053. Density at 60°F and 30 in Hg.: 1.3553 g. per liter, 0.08461 lbs. per cu. ft.

This element is most widely distributed in nature; 49.85 per cent of the solid crust of the earth, 88.89 per cent of water, and 20.8 per cent of air is oxygen. In air it exists in a free state. In a combined state, it exists in limestone, sand, marble, clay, quartz, iron ore, and many

other substances. It is prepared by merely heating certain of its compounds, some of which are mercuric oxide, potassium chlorate and manganese dioxide; by the decomposition of water by electrolysis; and from the air by purifying processes. Oxygen is a colorless, odorless, tasteless gas, heavier than air and slightly soluble in water. At a low temperature it is converted into a liquid which boils at -297.4°F . The phenomenon of ordinary burning or combustion is due to the chemical combination of oxygen with other substances. It unites with many elements to form a class of compounds, the

oxides. It is necessary to life. Animals die in an atmosphere of less than 16 per cent oxygen. Some important oxides are carbon dioxide (CO_2), carbon monoxide (CO), calcium oxide (CaO), magnesium oxide (MgO), ferric oxide (Fe_2O_3), and ferrosferric oxide (Fe_3O_4). The last two are important as ores of iron.

Hydrogen

Atomic Number, 1. Atomic Weight, 1.008. Molecular Weight, 2.0156. Specific Gravity: Hydrogen Standard, 1; Air Standard, 0.06959. Density at 60°F and 30 in. Hg.: 0.08526 g. per liter, 0.005323 lbs. per cu. ft.

Hydrogen does not occur in nature in a free state, but combined with oxygen it forms water, of which it constitutes 11.11 per cent. In a combined state it occurs also in the bodies of plants and animals, hence, in the volatile matter of coal, in petroleum, and in natural gas, of which it constitutes almost 25 per cent. Water is always one of the products of combustion when a fuel containing hydrogen is burned. It can be prepared by decomposing water with sodium, potassium, hot iron, hot coke, or the electric current; by treating certain metals with certain acids; and by treating aluminum with sodium or potassium hydroxide. Hydrogen is a colorless, tasteless, odorless gas, almost insoluble in water. It can be converted into a liquid that boils at -422.9°F . It is the lightest substance known, being about $\frac{1}{16}$ as heavy as air and $\frac{1}{8}$ as heavy as oxygen. It is combustible and explosive, and combines with oxygen in the weight proportion of 1:8 to form water. Its great tendency to combine with oxygen makes it a powerful reducing agent.

Sulphur

Atomic Number, 16. Atomic Weight, 32.066. Valences: II, IV, VI. Specific Gravity: monoclinic, 1.96; rhombic, 2.06.

This element occurs free in the neighborhood of volcanoes and in underground deposits, from which it may be prepared by purifying processes. In the combined state it is found as FeS_2 , FeCuS_2 , ZnS , and PbS , the last three being valuable ores of copper, zinc, and lead, respectively. It also occurs as the sulphates, CaSO_4 , BaSO_4 , and PbSO_4 , and in animal and vegetable matter. Compounds of sulphur occur in iron ores, in limestone, and in coal and sulphur from these sources combines with the iron in the blast furnace. If this sulphur is present in the iron in too large amounts, it is undesirable because of its possible injurious effects on steel and cast iron.

Sulphur is a brittle, yellow crystalline solid which melts to form a straw-colored liquid. It is allotropic, i.e., can exist in monoclinic, rhombic and amorphous forms. When heated to a sufficiently high temperature, it combines with oxygen to form sulphur dioxide (SO_2), with iron to form ferrous sulphide (FeS), and with most of the metals, forming sulphides. The sulphur in iron or steel is in the forms of FeS and MnS , distributed almost uniformly throughout the metal while in the molten state. Upon solidifying, however, owing to the difference in density and fusion temperature between these compounds and the metal, they may, under normal conditions, segregate to some extent, causing some parts of the solidified mass to show a higher content of this impurity than the average, or of the whole in the molten state. With hydrogen it forms hydrogen sulphide gas (H_2S)—very important in chemistry. Sulphur is used in the manufacture of matches and black gunpowder, also for disinfecting purposes, and for vulcanizing rubber. Its chief use, however, is in the manufacture of sulphuric acid (H_2SO_4), which is a very important material in modern civilization. This acid is obtained by oxidizing sulphur dioxide (SO_2), a gas given off in

the roasting of FeS_2 , ZnS , CuS , and from the burning of sulphur.

Carbon

Atomic Number, 6. Atomic Weight, 12.01. Valences: II, IV. Specific Gravity: amorphous, 1.8–2.1; graphite, 2.25; diamond, 3.51.

This remarkable element occurs free in nature in crystalline forms as diamonds and graphite and in the amorphous form as coal. It is the chief constituent of the bodies of plants and animals, of all natural fuels, and of nearly all prepared fuels. It occurs in combined state in limestone, magnesite, marble and other carbonate rocks. Carbon is allotropic; diamond and graphite are familiar. The common amorphous forms are coal, lampblack, charcoal, coke, and bone black. Its density varies with its form. It is infusible, but sublimes at about 3500°C .

Carbon forms many compounds with hydrogen, called hydrocarbons, such as methane (CH_4), ethylene (C_2H_4), benzene (C_6H_6) and acetylene (C_2H_2), each of which is but the first member of a series of related compounds. With oxygen it forms carbon dioxide (CO_2), which is a product of combustion and of respiration. CO_2 is also given off when carbonates, such as limestone, are heated. The reaction is, $\text{CaCO}_3 = \text{CaO} + \text{CO}_2$. Carbon monoxide (CO) is formed in combustion when the supply of oxygen is insufficient for the formation of CO_2 . Thus, in the blast furnace, a fixed amount of air is blown against an excess of hot carbon, which act results in this reaction: $2\text{C} + \text{O}_2 = 2\text{CO}$. Owing to its tendency to combine with oxygen, forming CO_2 , CO is a good reducing agent. So, the CO formed in front of the tuyeres in the blast furnace reacts with the iron oxide thus:

Carbon by itself acts as a reducing agent in the metalurgy of iron.

Iron forms a carbide with carbon, the formula of which is Fe_3C . Carbon is also found uncombined in pig iron in the form of tiny flakes of graphite; hence, the term graphitic carbon. Carbon has a marked effect upon iron. The varied properties of steel and the multiplicity of uses to which it can be applied are due largely to the influence of this element. Carbon in steel up to a certain limit is, therefore, not to be considered as an impurity but as an essential element.

Silicon

Atomic Number, 14. Atomic Weight, 28.09. Valence, IV. Specific Gravity, 2.42.

Next to oxygen, silicon is the most abundant element in nature. It is the most important constituent of the mineral part of the earth. Sea sand, quartz, jasper, opal and infusorial earths are almost pure forms of silica (SiO_2), the principal compound. As silicates, it occurs in clay, mica, talc, hornblende and feldspar. On account of its wide distribution, it forms the chief impurity of iron ore, as well as of nearly all natural mineral deposits. With carbon it forms the carbide, SiC (carborundum). It also forms several acids, chief of which is orthosilicic acid, (H_4SiO_4), which loses water when heated and forms SiO_2 .

Thus, in whatever form silicon may occur in an ore, it is looked upon as SiO_2 . This substance is the great acid of dry chemistry and at high temperatures will neutralize any base with which it comes in contact. In the blast furnace some of the silica (SiO_2) contained in

the charge is reduced to silicon. The amount so reduced varies with the working conditions of the furnace, mainly the temperature. Once reduced, the silicon alloys with the iron and becomes a part of the metallic bath. Most of this silicon is reoxidized and removed in the various processes of making steel. However, silicon is beneficial to steel, so it is sometimes added in small amounts to control the oxygen content and in larger amounts to form important alloy steels.

Nitrogen

Atomic Number, 7. Atomic Weight, 14.008. Molecular Weight, 28.016. Valences: III, V. Specific Gravity: Air Standard, 0.9673.

This element constitutes about 78 per cent of the Earth's atmosphere. It occurs in niter beds as saltpeter (KNO_3), and Chile saltpeter (NaNO_3), also in organic compounds and in coal. It is an odorless, tasteless, colorless, relatively inert gas. With hydrogen it forms ammonia (NH_3); with oxygen, a series of oxides, N_2O , NO , N_2O_3 , N_2O_4 , and N_2O_5 ; and with hydrogen and oxygen, an important acid, nitric acid (HNO_3). Its presence in the air as a diluent in so large amounts makes it an important factor in furnace practices. At lower temperatures it can be made to combine with iron to form a nitride which imparts some hardness even at low concentration.

Phosphorus

Atomic Number, 15.0. Atomic Weight, 30.975. Molecular Weight, 124.096. Valences: III, IV. Specific Gravity: white or yellow, 1.83; red, 2.05 to 2.34; black, 2.69.

Phosphorus, always combined with other elements, occurs widely distributed in limited amounts, particularly in soils. It is found in practically all iron ores. It occurs in deposits as phosphorite and apatite, and it is an important constituent of bone. While phosphorus belongs in the same group of elements as nitrogen, it does not resemble it very much from a physical standpoint. It is allotropic and exists in two forms, as a pale yellow solid that melts readily at the low temperature of 111.4°F , and as a red form quite different in properties. While it is a much more active element, it closely resembles nitrogen chemically. It forms compounds with hydrogen and oxygen, such as PH_3 and P_2O_5 . It generally is found in nature as salts of orthophosphoric (H_3PO_4) and pyrophosphoric ($\text{H}_4\text{P}_2\text{O}_7$) acids. With iron it forms a phosphide, Fe_3P . It is completely reduced in the blast furnace, hence practically all the phosphorus occurring in the raw materials is found in the pig iron. In steel it is an undesirable impurity, except for special applications. It can be partially removed as part of the slag by oxidation followed by neutralization of the oxide with lime.

Calcium and Magnesium

Calcium

Atomic Number, 20
Atomic Weight, 40.08
Valence, II
Specific Gravity: 1.54

Magnesium

Atomic Number, 12
Atomic Weight, 24.32
Valence, II
Specific Gravity: 1.74

While these two elements belong to different groups, they are very similar so far as the manufacture of iron and steel is concerned. With few exceptions one may be substituted for the other without great inconvenience. Their oxides are the more important bases of dry chemistry. Both elements occur as insoluble carbonates; limestone, marble, chalk, and marl are forms of calcium carbonate (CaCO_3). Magnesite is magnesium carbonate (MgCO_3). When heated, both of these compounds de-

compose into their oxides and carbon dioxide, thus:

CaO represents quicklime, and MgO, magnesia.

These elements also occur together as a double salt of carbonic acid, named calcium magnesium carbonate, $\text{CaMg}(\text{CO}_3)_2$, commonly called dolomite, which gives calcium magnesium oxide, $\text{CaO}\cdot\text{MgO}$, when calcined.

Both calcium and magnesium may be obtained electrolytically from their chloride. Magnesium is also obtained electrolytically from its oxide or by chemical reduction, involving a reducing agent (carbon in one process and ferrosilicon in another), followed by distillation and recovery of the magnesium metal from the distillate.

Lime (CaO), magnesia (MgO), and the double oxide, $\text{CaO}\cdot\text{MgO}$, are all very refractory, but on account of its tendency to slake in air, CaO is not used as such. Practically, MgO is the best basic refractory known, and calcined dolomite is the best available substitute. The oxides are reduced with difficulty, and on account of their cheapness constitute the principal basic fluxes. As MgO is the leading basic refractory, CaO is the leading basic flux. It combines with both silica and phosphoric acid to form readily fusible slags, which have a lower density than iron and consequently float upon the surface of the metallic bath.

Aluminum

Atomic Number, 13. Atomic Weight, 26.98. Valence, III. Specific Gravity: 2.7.

This element in combined form is very widely distributed, occurring as one of the constituents of feldspar, granite, mica, cryolite, and all clays. It is reduced from the oxide, Al_2O_3 , by an electrolytic process, in which a molten bath of cryolite acts as a solvent. It has a strong affinity for oxygen, violently reducing iron oxide, and on this account it is added to steel as a deoxidizing agent. In its compounds aluminum displays decidedly basic properties, forming salts with all the common acids except carbonic acid. In wet reactions, it forms neither a carbonate nor a sulphide, but it readily combines with sulphur at high temperatures. Aluminum hydroxide, $\text{Al}(\text{OH})_3$, however, acts like both an acid and a base. When this compound is heated, it loses water and forms alumina (Al_2O_3), which is found in varying amounts in all the raw materials that enter into the metallurgy of iron. In the blast furnace alumina is never reduced. Its presence, however, has a marked influence on the slag, affecting its fluidity and fusion temperature, important considerations in blast furnace practice. In its purer states alumina is a good refractory, but the cost of production makes its extensive use as such prohibitive. An extended list of other metals are added to the metal aluminum to produce stronger alloys; e.g., Cu, Mg, Si, etc.

Chromium

Atomic Number, 24. Atomic Weight, 52.01. Valences: II, III, VI. Specific Gravity: 6.9.

This element is somewhat rare. In small deposits it is found as chromite, $\text{Cr}_2\text{O}_3\cdot\text{FeO}$, the best neutral refractory known, which, in its purer states, melts at about 3450°F . Chromium is obtained by reduction of its oxides with aluminum or silicon. It is white, crystalline, very hard and does not tarnish. Chromium forms both acid and basic compounds. It is very important in the manufacture of the stainless and other alloy or special steels.

Its chief physical effect is one of facilitating quench hardening, hence it is employed to increase the hardenability of projectiles, armor plate, automotive steels, and tool steels. Chromium is added to alloy steel in the form of ferrochromium, an iron-chromium alloy produced from ores.

Manganese

Atomic Number, 25. Atomic Weight, 54.93. Valences: II, III, IV, VI, VII. Specific Gravity: 7.4.

This element occurs in nature as MnO_2 , its deposits being somewhat limited in the United States. In very small amounts it is widely distributed, and is found in most of the raw materials used in the manufacture of pig iron. About 75 per cent of this manganese is reduced in the blast furnace, and becomes a constituent of all pig iron. It is readily oxidized in the purifying processes and, except for relatively low amounts, the manganese found in steel is added to it in the process of manufacture. Its effect in steel is beneficial because it offsets to some extent the harmful effects of oxygen and sulphur. Higher percentages, 10 per cent to 15 per cent, are employed to produce the special steel known as Hadfield manganese steel.

Iron

Atomic Number, 26. Atomic Weight, 55.85. Valences: II, III. Specific Gravity: 7.864.

This most important metal occurs combined with other elements. It is found in varying amounts in nearly all earthy matter, such as clays, soils, sands, etc. In deposits, it is found as the sulphide (FeS_2), as silicates, as a constituent of chromite, as the carbonate ($FeCO_3$) and as the oxides Fe_2O_3 and Fe_3O_4 . The compound last named is magnetic. Pure iron is grayish-white in color and relatively soft when compared with steel of high carbon content. It is malleable, ductile, and magnetic. The melting point of the pure metal is about $2800^\circ F$, but the usual commercial forms melt at lower temperatures. The presence of certain elements, notably carbon, silicon, phosphorus, or sulphur, in the metal lowers the melting point markedly. Iron forms two series of compounds, the ferrous and the ferric. The more important ferrous compounds are FeO , $Fe(OH)_2$, $FeCl_2$, $FeSO_4 \cdot 7H_2O$; corresponding ferric compounds are Fe_2O_3 , $Fe(OH)_3$, $FeCl_3$, $Fe_2(SO_4)_3$. Most of these compounds are of the highest commercial importance, and many will receive a more thorough treatment later in this book.

Chapter 2 (Continued)

SOME FUNDAMENTAL PRINCIPLES OF CHEMISTRY AND PHYSICS

PART 3 — FUNDAMENTALS OF PHYSICS

SECTION 1

INTRODUCTORY

Physics is a science that deals with matter, energy, and radiation. Most of the discussion on the structure and properties of matter, usually included among the subjects that are related to Physics, already has been presented in Part 1 of this chapter, and need not be repeated here. In the following summary of physical

theories and facts, only those phases of physical knowledge which are essential to an understanding of the manufacture and use of steel are considered; subjects such as mechanics, sound, light and nuclear physics are not discussed since they are not directly involved in an understanding of later chapters of this book.

SECTION 2

ENERGY, FORCE, WORK AND POWER

Nature of Energy—Physics and chemistry are concerned with more than matter. The human senses are aware of a second fundamental factor in nature, called energy, which is not a material thing and is difficult to define satisfactorily. Energy is that which gives a body the ability to move against a resistance, that is, to do work.

Potential vs. Kinetic Energy—In general, there are two classes of energy; namely, kinetic energy and potential energy. Kinetic energy is the energy possessed by a body by virtue of its motion; for example, a moving train, a rotating wheel, and a bullet in flight all have kinetic energy. Potential energy, sometimes called stored energy, is the energy possessed by a body because of its position, or due to its chemical or physical state; for example a weight suspended in the air, an electric storage battery, a charged electric condenser, and a piece of coal all possess potential energy.

It is a matter of common observation that potential energy can be changed into kinetic energy, and vice versa; thus, a pendulum on the down-swing converts potential energy into kinetic energy, which is then reconverted into potential energy on the up-swing. Furthermore, it is true that the amount of potential energy expended is equal to the amount of kinetic energy generated, except for a certain small amount which is lost due to friction in the air and at the supports. It is this loss which prevents the realization of "perpetual motion."

Forms of Potential Energy—There are several forms of potential energy; namely, mechanical, electrical, thermal, and chemical. Furthermore, there are at least two kinds of stored mechanical energy, that is gravitational potential energy, or energy of position, and elastic

potential energy, or energy of distortion; for example, a weight suspended in air possesses gravitational energy because it will do work when it falls, while a wound clock spring possesses elastic energy, since it can do work when it unwinds. Electrical energy may be stored in a condenser, thermal or heat energy in a radiator, and chemical energy is stored in a storage battery or in a piece of coal.

Conversion of Energy—Casual observation reveals that one form of energy can be transformed to another form. An electrical power plant affords an illustration of a complicated transformation of energy. Part of the chemical energy in coal is converted into heat energy which in turn is converted into mechanical energy in steam; the energy of the steam is transferred to the moving machinery of a turbine and thence to a generator which converts this mechanical energy into electrical energy. This electrical energy is transmitted over wires to some distant point where it is reconverted into heat, light, or mechanical energy.

Conservation of Energy—Early experiments on the conversion of mechanical energy into other forms of energy led to the general conclusion that the original amount of energy can always be completely accounted for after such a change. In other words, energy can neither be created nor destroyed, it can only be transformed. This is known as the **Law of Conservation of Energy**. As pointed out previously, recent work in nuclear physics has demonstrated that matter can be converted into energy; that is, in a sense energy can be created; however, in all common chemical and physical phenomena and processes, this exception need not be taken into consideration, since the principle still holds.

Force—It has already been stated, in connection with the force of attraction of gravity exerted by the earth on all objects, that force is perceptible and is associated with muscular effort in lifting or pushing an object. This simple conception is quite satisfactory for engineering purposes with one reservation; namely, that force must be considered a vector quantity; that is, both its magnitude and its direction must be given in order to completely define it. It is clear that when a body is lifted vertically the force of gravity which must be overcome is acting in a direction opposite the motion of the body, so that the applied force required is equal to the weight of the body. However, in pushing the same body along the ground, the force required is not equal to the weight of the body, because the force of gravity acts vertically, whereas the applied force is directed horizontally; actually, only enough force must be exerted in the direction of motion of the body to overcome the friction between the body and the ground.

Work—The concept of work has developed naturally in connection with the lifting of a weight through a definite distance. Thus, if an object of a certain weight is lifted a certain distance, and then is lifted twice as high, it is intuitively felt that twice as much work has been done in the second case. Similarly, if the weight of the object is doubled, the work expended in lifting the object a certain distance is also doubled. In other words, the work done in moving a body is equal to the product of the applied force and the distance moved in the direction of the force. Expressed mathematically:

$$W = wd$$

where "w" is the weight of the body expressed in pounds or newtons, "d" is the distance the body is moved in the direction of the force expressed in feet or meters, and "W" is the work which is measured in foot-pounds or newton-meters. One newton-meter is also called a joule. Sometimes another metric unit of force, the dyne (equal to 1/100,000 of a newton), is used; in this case, the unit of work is the dyne-centimeter, which is more commonly called the erg. One joule is equal to ten million ergs. It is apparent that energy and work are meas-

ured in the same units, since expended energy is called work, or energy may be thought of as virtual work.

Power—The time required to do a given amount of work is usually an important factor. For example, a person may not be able to carry a heavy object to the top of a steep hill in a few minutes, but this may be possible within a few hours; the difference is merely a matter of time. The rate of doing work, or of expending energy, is called power. In mathematical terms:

$$P = \frac{E}{t}$$

where "E" is energy or work expressed in foot-pounds or joules, "t" is the time in seconds, and "P" is the power measured in foot-pounds per second, or joules per second. One joule per second is also called a watt. Before the machine age, the basis for measurement of power was the rate at which an average horse could do work; this standard rate was termed a horsepower. Obviously, such a standard could not be made precise and was not practical to maintain, so eventually it was agreed that

1 horsepower = 550 foot-pounds per second
or 1 horsepower = 746 watts (or joules per second)

Transmission of Energy—Another very important and useful characteristic of energy, aside from its capacity for conversion from one form to another, is that it can be transmitted from place to place over rather long distances. Thus, electrical energy can be generated at a central station located near a coal supply or waterfall, and this energy can be conveniently transmitted to distant towns and farms, or steel mills or other industrial plants where it can be converted into useful mechanical work. Other forms of energy also can be transmitted, although usually over shorter distances; for example, heat from a furnace can be transferred to radiators in the different rooms of a building through the medium of water, steam, or air, and mechanical energy can be transmitted by means of wheels, axles, levers, and rods.

SECTION 3

HEAT

Nature of Heat—It was originally believed that combustion was concerned with a mysterious stuff called phlogiston which was somehow released by all substances when they burned, or that water over a fire became hot because a subtle weightless fluid called caloric was added to it. Thus, the early tendency was to consider heat as an intangible kind of matter, rather than a form of energy. Later experiments on the temperatures developed from the friction of moving mechanical parts showed that the temperature rise was proportional to the amount of mechanical work done; this led to the conclusion that mechanical energy could be converted into heat and that heat must be a form of energy. Further work demonstrated that heat itself is some sort of internal motion and that it is in fact the motion of the atoms and molecules which constitute matter.

Temperature—The human body is aware of temperature through the sensations of hot and cold; that is, temperature refers to hotness, and the term usually implies the quantitative measurement of hotness by some more accurate means than the human senses. The temperature of a region of matter is a quantity that depends on the average kinetic energy of the atoms or molecules

in that region. The atoms or molecules of any substance are in a rapid and continual motion, and all types of atoms and molecules at the same temperature have the same kinetic energy. When heat energy is added to a body in a fixed state, the average speed of its molecules is increased, and its temperature rises proportionally to the increase in average molecular kinetic energy. The temperature is truly zero only when all molecular motion ceases, and this point is called absolute zero.

The simplest temperature scale, and the most convenient for scientific purposes, is one which has its zero-point based at absolute zero. Such a scale exists, and is known as the absolute or Kelvin scale; however, the temperature scales in everyday use are based arbitrarily on the freezing and boiling points of water; the temperature interval between these two fixed points being subdivided into small increments called degrees. On the Centigrade scale, used in ordinary engineering and scientific work, the zero point is based at the freezing point of water and the boiling point of water is assigned the temperature of 100 degrees, so that there are one hundred equal subdivisions or degrees between these two points. The absolute or Kelvin scale uses the same

size divisions or degrees as the Centigrade scale, although its zero point is based at absolute zero, rather than at the freezing point of water. In the Fahrenheit scale, which is in common use in all English-speaking countries, 32° F is based at the freezing point of water and 212° F is based at the boiling point of water; thus, there are 180 equal subdivisions or degrees between these two fixed points. The relationship between these three temperature scales is shown below:

Fixed Point	Absolute	Centigrade	Fahrenheit
Absolute zero	0°	-273°	-459°
Freezing point of water.	273°	0°	32°
Boiling point of water..	373°	100°	212°

The conversion of temperatures from the Centigrade to Fahrenheit scales, or vice versa, can be accomplished by substitution in the following expressions:

$$F = (9/5 C) + 32$$

$$C = 5/9 (F - 32)$$

where "F" is the temperature in degrees on the Fahrenheit scale and "C" is the temperature in degrees on the Centigrade scale.

Thermometry and Pyrometry—In principle, any physical phenomenon that varies systematically with temperature can be used to measure temperature. Most solids, liquids, and gases expand with increasing temperature, and the amount of expansion is commonly used as an indicator of temperature. Mercury and alcohol expand considerably with moderate increase in temperature, and hence are used in glass-enclosed thermometers for measuring ordinary temperatures. Mercury solidifies at -38.2° F (-39° C) and boils at 675° F (357° C), whereas alcohol freezes at -178.6° F (-117° C) and boils at 173.3° F (78.5° C), so that thermometers employing these substances can only be used within these ranges. Other properties of matter are used to measure temperature. Of course, all of these methods require calibration against fixed reference points in the temperature scale, such as the freezing and boiling points of water, or the melting points of pure metals.

Two solids, such as copper and iron, having quite different thermal expansion coefficients can serve as a thermometer if joined together in the form of a "bimetallic strip." On heating, the copper expands more than the iron, and the strip bends one way; on cooling, the copper contracts more than the iron, and the strip bends the other way. The position of the end of the strip can be used to indicate the temperature.

When two wires of dissimilar metals, such as copper and iron, are joined at one end, an electromotive force (e.m.f.) is generated, which results in a difference in electrical potential (voltage) between the two free ends of the wires, if there is a difference in temperature between the junction and the free ends, and this difference in voltage is proportional to the difference in temperature; thus by using an instrument for measuring the voltage (voltmeter or galvanometer), the temperature can be determined. This device is called a thermocouple.

The resistance of an electrical conductor, such as a metal wire, varies enough with temperature for the measurement of resistance to provide an excellent precision method of determining temperature over a wide range. This principle is utilized in resistance thermometers.

Still another type of thermometer employs optical principles for temperature measurement. The color of a hot, glowing body varies with the temperature. Comparison of the color of this object with the color of a

controlled hot filament of an electric light permits very high temperatures to be measured. Such a device is called an optical pyrometer.

The intensity of the light given off by a hot, glowing body also changes with the temperature, and thus by measuring the light intensity, or comparing it to certain standard intensities, the temperature can be determined. This principle is utilized in radiation pyrometers.

Measurement of Heat—In the conversion of mechanical energy to heat energy through friction, the temperature rise in the heated object is nearly proportional to the amount of mechanical energy transformed; furthermore, it is found that to raise the temperature of 10 kilograms of water 1° C requires ten times as much heat energy as is needed to raise the temperature of 1 kilogram of water 1° C. Therefore, the change in heat energy of a body, that does not change state in this temperature range, is proportional both to the temperature change and to the mass of the body. From this, it is clear that temperature and amount of heat energy are two entirely separate and distinct quantities, although they are related.

Heat energy could be measured in units of foot-pounds or joules, but because the methods of heat measurement are not ordinarily related to mechanical effects, a special and more convenient unit of heat energy is used. In the metric system, changes in heat energy are expressed in kilocalories. A kilocalorie (1000 calories) is the amount of heat energy that must be added to one kilogram of water to raise its temperature 1° C. In the English system, the unit of thermal energy is the British Thermal Unit (abbreviated Btu), which is the amount of heat required to increase the temperature of one pound of water 1° F. One Btu is equivalent to about 0.252 kilocalories.

The heat required by various substances to raise their temperatures the same amount differs considerably. In order to express differences of this sort quantitatively, the concept of specific heat is used. In the metric system, specific heat is defined as the number of kilocalories per kilogram of a certain substance that is required to change the temperature of the substance by 1° C. This provides a simple way to express the change in heat energy of any substance when its temperature is changed:

$$\text{Change in heat energy} = MS(T_2 - T_1)$$

where "M" is the mass in kilograms, "S" is the specific heat of the substance in kilocalories per kilogram per degree Centigrade, and "T₂" and "T₁" are the final and initial temperatures, respectively, in degrees Centigrade.

Heat vs. Changes in State of Matter—As previously mentioned, when a substance undergoes a change of state it also suffers a change in heat energy. Thus, when a solid substance melts, it absorbs a certain definite amount of heat energy (per unit mass of material) from its surroundings, and when it resolidifies, it releases this same quantity of heat; this is known as the heat of fusion of the substance. Similarly, when a liquid substance boils or condenses, it absorbs or evolves a certain definite quantity of heat, called the heat of vaporization of the substance.

Another kind of change in state of matter, that involves a change in heat energy, is a change in the crystal structure of a solid substance. For example, solid iron undergoes a rearrangement of its atoms at about 1650° F (900° C), whereby its crystal structure changes from a body-centered (alpha) to a face-centered (gamma) cubic lattice of atoms; this change is accompanied by a change in heat energy, amounting to about 4 calories per gram, which is called the heat of transformation.

Such changes in crystal structure are called **polymorphic** or **allotropic changes**. As in the cases of melting and boiling, the temperatures at which these changes occur are affected by pressure, but at ordinary atmospheric pressure they are constant and characteristic of the substance and the particular transformation.

Conversion of Heat into Mechanical and Electrical Energy—The conversion of mechanical energy into heat energy has already been discussed and it has been pointed out that the ratio of the amount of heat generated to the mechanical energy expended is a constant called the **mechanical equivalent of heat**. In the metric system, 1 calorie = 4.186 joules, and in the English system 1 Btu = 778 foot-pounds. Industrially, the change of mechanical energy to heat energy is not nearly as important as the reverse change of heat energy to mechanical energy, for the burning of coal or oil to produce heat and, in turn, mechanical energy in steam turbines and internal combustion engines, has been the world's greatest source of useful work. Heat can also be converted directly into electrical energy, as in thermocouples, or electrical energy can be converted directly into heat energy, as for example, in electric heaters and resistance furnaces, wherein a heavy electric current is passed through a poor electrical conductor. The electrical equivalent of heat is given by the expression:

$$\text{Change in heat energy} = 0.24 IRt$$

where "I" is the electrical current measured in amperes, "R" is the resistance measured in ohms, and "t" is the time in seconds. The ampere and ohm are defined in Section 7 of this part of Chapter 2.

Effects of Temperature on Physical Properties—Heat is capable of producing marked changes in the physical properties of matter. Adding heat to a gas or liquid increases its molecular energy, and thus increases its pressure or volume. Solids expand when heated and the amount of expansion (thermal coefficient of expansion) differs for every substance and, frequently, it is different for the same substance at different temperatures. Changes in heat energy, and thus in the temperature or state of a substance, are usually accompanied by changes in its mechanical properties (modulus of elasticity, ductility, hardness, and tensile strength), in its electrical properties (conductivity), and in its magnetic properties (permeability).

Heat Flow—Heat energy may be transferred from place to place by three different mechanisms—conduction, convection, and radiation.

a. Conduction—When heat flows through a body by the transference of the kinetic energy of individual atoms or molecules without mixing, it is said to flow by **conduction**. When one end of a bar is heated, the atoms or molecules are given greater vibratory motion, that is, greater kinetic energy; in some way, probably by collisions, these atoms or molecules share this increased energy with their neighbors, which in turn pass this energy along to those beyond, and so on. Thus, the energy of agitation (heat) is propagated along the bar.

The measurement of heat flow by conduction is most easily understood in connection with solids, since in this case, convection is not present, as it is in liquids and gases, to complicate the situation. The basic law of heat transfer can be written in the form of a rate equation:

$$\text{Rate} = \frac{\text{Driving Force}}{\text{Resistance}}$$

in which the driving force is the temperature difference across a solid body, since it is apparent that heat can flow only when there is an inequality of temperature. This law, known as **Fourier's Law**, states that the rate of

heat flow through a body is proportional to the temperature drop, to the area, and inversely proportional to the thickness of the body. The mathematical expression of Fourier's Law is:

$$\frac{Q}{t} = \frac{kA(T_2 - T_1)}{L}$$

where "Q" is the amount of heat energy transferred in time "t," "A" is the area of the body perpendicular to the direction of heat flow, and "(T₂ - T₁)" is the temperature difference between opposite sides or ends of the body, "L" is the thickness of the body in the direction of heat flow, and "k" is a constant which is defined by this equation and is called the **thermal conductivity** of the particular substance constituting the body. If "Q" is measured in Btu, "t" in hours, "A" in square feet, "T₂" and "T₁" in degrees Fahrenheit, and "L" in feet, then k is expressed as Btu per hour per square foot per degree Fahrenheit per foot.

When each of the terms in the equation defining "k" is equal to one, "k" is termed the **coefficient of thermal conductivity**. The numerical value of the coefficient of thermal conductivity depends upon the substance of which the body is made and upon its average temperature. The thermal conductivities of liquids and gases are very small in comparison with those of most solids. For example, at 212° F the thermal conductivity of silver is 240 Btu per hour per square foot per degree Fahrenheit per foot, that of building brick is about 0.8, that of water about 0.35, and of air 0.017. In general, the variation of conductivity with temperature is linear, that is,

$$K = a + bT$$

where "a" and "b" are constants and "T" is the temperature.

It is of interest to note that thermal conductivity and electrical conductivity are closely related. In general, the best electric conductors have the highest thermal conductivity. The relationship between thermal and electrical conductivities is given by the **Wiedemann-Franz Law**:

$$\frac{K}{\sigma} = aT$$

where "K" is the thermal conductivity, "σ" is the electrical conductivity, "T" is the absolute temperature, and "a" is a proportionality constant. This law holds fairly well for most metals within restricted temperature ranges.

b. Convection—When heat flows by actual mixing or physical turbulence, the mechanism is known as **convection**. Convection is restricted to heat flow in liquids and gases. It is practically impossible for heat to flow through fluids by pure conduction without some convection, because of the eddies set up by the changes of density in the fluid with temperature. For this reason, the terms conduction and convection are frequently used together, although in many instances, the predominant mechanism is convection; for example, the heating of a room by a steam radiator is largely a matter of convection. The heating of a room by a hot-air furnace is an example of almost pure convection.

In the transfer of heat from a solid body to a liquid, a thin, comparatively stagnant film of liquid exists at the surface of the solid, which is of great importance in determining the rate of heat transfer. Heat is transferred through this thin, stationary, fluid film more by conduction than by convection, and since the thermal conductivities of fluids are very small, the rate of heat transfer is very slow. In many processes, such as the

quenching of steel, the heat transfer through the surface film of liquid on the steel is the limiting factor which controls the rate of cooling of the steel. In general, the greater the turbulence in the liquid and the lower its viscosity, the thinner the stagnant film and the higher the rate of heat transfer.

c. Radiation—The transfer of energy through space by means of electromagnetic waves is termed radiation. If radiation travels through empty space, it is not transformed to heat or any other form of energy, nor is it diverted from its path. If, however, matter appears in its path, the radiation will be absorbed or reflected. It is only the absorbed energy that appears as heat, and this transformation is quantitative. Thus, a polished opaque surface or mirror will reflect most of the radiation striking it, whereas a black or matte surface will absorb most of the radiation received by it and will transform such absorbed energy quantitatively into heat.

In practice, radiation is an important method of transferring heat, which is especially true in the making and treating of steel where furnace temperatures are relatively high. The fundamental law covering heat transfer by radiation, known as Stefan's Law, states that the total energy which is radiated by a body per second is proportional to its surface area and to the fourth power of its absolute temperature. In mathematical terms,

$$E = cAT^4$$

where "A" is the area of the radiating surface in square feet, "T" is the temperature of the body in degrees absolute, "c" is a constant equal to 1.72×10^{-8} , and "E" is the total energy given off per second in Btu.

Actually all bodies at temperatures above absolute zero radiate energy according to Stefan's Law. Thus, in the case of a small body of temperature " T_1 " and area "A" completely surrounded by a hotter body of temperature " T_2 ," the net amount of heat transferred per second from the hotter body to the colder body is the algebraic sum of the radiation from the two bodies; thus, Stefan's Law may be written:

$$e = cA (T_1^4 - T_2^4)$$

where "e" is the net amount of heat transferred from the hotter body to the colder per second, " T_1 " is the absolute temperature of the hotter body, and " T_2 " is the absolute temperature of the colder body. This assumes, however, that all of the heat radiated by either body falls on the other body and is absorbed by it. In practice, most objects do not fulfill this last assumption. Instead of absorbing all of the radiant energy that falls on them, they absorb only a part of it and reflect the rest. Only an ideal black body absorbs all, and reflects none of the radiant energy falling on it. Most objects with a matte black surface approach the theoretical black body closely enough for practical purposes; polished metal bodies and white bodies, on the other hand, deviate widely from the ideal black body. It is true, however, that inside a closed space, where the temperature is uniform throughout, all objects, no matter what their substance, color, or surface condition, behave as black bodies. This greatly simplifies radiation calculations and measurements in many important cases; thus the interior of a furnace may be considered to be uniform to the extent that all objects in it may be assumed to be black.

SECTION 4

MAGNETISM AND MAGNETIC FIELDS

Natural Magnets—Certain rocks have long been known to possess the ability to attract iron and are called natural magnets. These rocks are now recognized as magnetite (Fe_3O_4), an iron ore. The term magnetism refers to this ability to exert forces on a piece of iron from a distance. When elongated pieces of such rocks are freely suspended from threads, or floated by some suitable means on water, they orient themselves with their longest axis in a north-south direction; in this form, they represent the earliest crude form of compass, which led to their being called lodestones or "leading stones." The north-seeking end or pole of the piece is called the north pole of the magnet and the south-seeking end is called the south pole. The attractive force of any magnet is greatest at its ends, or poles.

Artificial Magnets—Lodestones today are merely scientific curiosities, since it is possible to make artificial magnets that are far stronger than natural ones, and in shapes most convenient for their intended use. Familiar forms are the bar magnet and the horseshoe magnet. One method for making an artificial magnet is to stroke, with another magnet, the material to be magnetized. In another method, the material to be magnetized is placed inside a coil of wire carrying a current of electricity. The most modern method consists of suspending the piece to be magnetized on a conductor carrying a heavy electric current. The last two methods are possible because, as will be learned later, there are magnetic effects caused by electric currents.

If the material being magnetized is relatively soft (pure) iron, only a light electric current is necessary to magnetize the piece, but the result is only temporary. If

hardened steel is used for the magnet, it requires a heavier electric current and a longer time to produce a magnet, but once magnetized the steel will retain its magnetic properties for a long time. Magnets made from materials which lose their magnetism readily are called temporary magnets while magnets made from steel and other materials that retain their magnetism are called permanent magnets. Permanent magnets are commonly made from steel. Tungsten steel and alloys containing cobalt are used extensively. An alloy of aluminum, nickel and cobalt also is used where very strong magnets are to be made.

Magnetic Fields—Two magnet poles in the same vicinity exert forces on each other. They repel each other if they are like poles (both north poles or both south poles), attract if they are unlike. In the region about each of the poles a magnetic field of force exists; that is, any magnetic pole there would experience a force proportional to the field strength. The variation in the direction and strength of the magnetic field about a bar magnet can be demonstrated by placing a sheet of paper over a magnet and sprinkling iron filings over it. The iron filings will assume a pattern similar to that shown in Figure 2-11, the number and direction of the lines depending on the strength of the magnet. The chains of filings show the direction of the lines of force in the magnetic field. What apparently is empty space, definitely contains energy, for the particles of iron making up the filings experience forces which move them into the indicated pattern. It should be remembered that this same field completely surrounds the magnet, and that the pattern shown by the filings in this experiment

FIG. 2-11. Pattern assumed by iron filings scattered on a sheet of paper or glass placed over a bar magnet.

represents only a cross section of the magnetic field. The lines of force are assumed to emanate from the north pole of the magnet and to reenter it at the south pole.

Earth's Magnetic Field—The earth itself is a huge natural magnet, having magnetic poles like any other magnet, and possessing a magnetic field. A lodestone, or a magnetized needle (compass) always aligns itself in a north-south direction because it is acted upon by the earth's magnetic field of force. The lodestone or needle aligns itself with the lines of force of that field. It is interesting to note that the magnetic pole of the earth which attracts the north (or north-seeking) pole of a magnet is actually a magnetic south pole, and vice versa. It also may be noted that the magnetic poles of the earth do not coincide with the geographic poles, and that the earth's magnetic field is neither uniform nor constant.

Magnetic Field Strength—Magnetic field strength or magnetizing force is measured in terms of force acting on a unit magnetic pole. A unit pole is defined in such a way that two unit poles placed one centimeter apart in air repel each other with a force of one dyne. A dyne is defined as that force which will give a mass of one gram an acceleration of one centimeter per second per second. The unit of field strength, the gauss, is a force of one dyne exerted by the field on a unit magnetic pole. The field strength is also commonly expressed in terms of the number of lines of force intersecting a unit area perpendicular to the direction of the field; the lines of force are numerically equal to the field strength in gauss. Magnetic flux refers to the total number of lines of force passing through a section of a magnetic field, and it is equal to the product of the area and the field strength. The unit of magnetic flux, the maxwell, is the flux through an area of one square centimeter perpendicular to a field having a strength of one gauss.

Magnetic Induction—Materials capable of being attracted by a magnet or of acquiring magnetism from a magnet are called magnetic materials. Magnetism may be imparted to magnetic materials by bringing them into direct contact with a magnet or by bringing them into a magnetic field. The degree of magnetism induced will depend upon the strength of the magnetic field. For example, a small piece of soft iron in contact with one of the poles of a bar magnet, so long as it is in contact, will itself act as a magnet and attract other pieces of iron. Similarly, a piece of soft iron bar adjacent to, but not in contact with, one of the poles of a bar magnet will be magnetized. In this latter case, if one end of the soft iron bar is adjacent to the south pole of the bar magnet, that end of the soft iron piece will become a

north pole and its opposite end will become a south pole. This can be demonstrated by the action of the end of the soft iron piece farthest from the bar magnet upon a magnetic needle or compass (Figure 2-12). In neither

FIG. 2-12. Magnetism imparted to pieces of soft iron (a) by contact with magnets and (b) by bringing a piece of soft iron into a magnetic field.

of the above cases is the soft iron itself a magnet except when in contact with, or influenced by, the magnetic field of the bar magnet. The kind of magnetism exhibited by the soft iron is said to be **induced** and the action is called **magnetic induction**. The magnetism induced in soft iron is temporary, but permanent magnetism may be induced in hardened steel if the bar magnet used is strong enough, depending upon the degree of hardness of the steel.

Among the commoner magnetic materials are soft (pure) iron as referred to above, nickel, cobalt, manganese and chromium. Pure iron, however, possesses the best magnetic properties. Magnetic materials offer very little resistance to the passage of lines of force. A magnetic field will pass through a nearby piece of iron rather than take a shorter route through the air because of the lower magnetic resistance of iron as compared to air (Figure 2-13). Non-magnetic materials, e.g., cop-

FIG. 2-13. Field distortion caused by soft iron bar.

per and aluminum are not attracted to magnets nor will they attract a magnet. Some alloy steels are non-magnetic, and some elements lose their magnetic properties when heated.

Permeability—Any substance capable of acquiring magnetic properties when under the influence of a magnetic field is said to be **permeable**. Permeability is measured by the number of lines of force which can be concentrated within a unit area of the material. All materials have a **saturation point** beyond which it is impossible to concentrate any more lines of force within a unit area. Soft iron is an example of a highly permeable material.

Retentivity—The degree to which the material resists becoming magnetized or losing its magnetism is the **retentivity** of the material. Soft iron is highly permeable,

but it loses its magnetism almost immediately after being removed from the magnetic field, and thus has a low degree of retentivity. Hard steel, however, can be made into a permanent magnet by being acted upon by a magnetic field and thus has a high degree of retentivity.

Reluctance—The opposition to passage of magnetic lines of force characteristic of a given material is termed its reluctance. The reluctance of a magnetic circuit is directly proportional to the length of the circuit, and inversely proportional to its section. Ordinarily, magnetic materials exhibit less reluctance than non-magnetic materials. Also, non-magnetic materials have practically the same reluctance at all flux densities, while the reluctance increases with the flux density (number of lines of magnetic force) for magnetic materials.

Theory of Magnetism—Actually, all materials are magnetic, although most of them are only about one-millionth as magnetic as iron. The ultimate source of magnetism is not well established, but evidence points to the molecules and atoms constituting matter. According to an older theory, the atoms are considered to be tiny magnets themselves, some much stronger than others. In ordinary materials, the atomic magnets are

oriented at random, and their effects normally cancel each other. In the case of iron, each atomic magnet, when placed in a magnetic field, tries to line up with the field; if more of these atomic magnets line up in one direction than in any other, their effects are additive, so that the whole piece becomes a powerful magnet. However, if this iron magnet is heated to a dull red color, the alignment of the atomic magnets is so disturbed by thermal vibration that the piece of iron loses its magnetism. At present, this older belief has been modified to regard discrete portions of a body undergoing magnetization as becoming successively magnetized. These portions involve groups of atoms instead of single atoms, and are referred to as **domains**. The effect of temperature in destroying natural magnetism in a body is conceived to be the result of the sudden breaking-up of the arrangement of atoms forming domains when some definite temperature (the Curie point) is reached.

According to either theory, every magnetic substance has a saturation point beyond which the magnetic flux density cannot be increased because, once all the elementary atomic magnets in a substance are lined up, or all possible domains are established, not much further increase in magnetism can be obtained.

SECTION 5

ELECTROSTATICS

Nature of Electrostatic Charges—According to the concept of the structure of matter outlined in Part 1 of this chapter, the nucleus of any atom is composed of protons and neutrons and carries a positive charge that is exactly balanced by the sum of the unit negative charges of the electrons in the electronic system surrounding the nucleus. All matter, therefore, normally is uncharged or neutral. However, if certain substances are rubbed together, some of the electrons can be "scraped off" the surface of the one and added to the surface of the other. Thus, if a glass rod is rubbed with silk, electrons are transferred from the surface of the glass to that of the silk. The silk, with an excess of electrons, then carries a negative charge, and the glass which is left with less than its normal quota of electrons acquires a positive charge. In a similar manner, if a hard-rubber rod is rubbed with fur, the rod acquires a negative charge while the fur becomes positively charged. These charges, designated as **electrostatic charges**, constitute what is known as **static electricity**, so called because the charges are at rest. Charged bodies are said to be **electrified**. Bodies having a positive charge, due to a deficiency of electrons, are said to be at a higher potential than those carrying a negative charge resulting from an excess of electrons.

FIG. 2-14. Distribution of charge of conductors.

An electrostatic charge is distributed over the surface of an electrified body. The density of the charge at any part of the surface depends upon the shape of the body. For example, a charge on an electrified sphere is distributed uniformly over the surface of the sphere. In the case of an egg-shaped body, the greater part of the charge is concentrated at the sharper end of the egg; on a uniform rod, there is a concentration of charge at each end. (Figure 2-14).

Electrostatic charges can be transferred from one body to another by contact. A pith ball, if touched by a positively charged glass rod, will have some of the positive charge imparted to it. If a second pith ball, positively charged in the same manner, is brought near the first positively charged ball, the two will mutually repel each other. If both balls are charged negatively by contact with a negatively-charged rubber rod, they again will repel each other. However, if one ball is given a positive charge and the other is given a negative charge, the two balls will mutually attract each other. Thus, like electrostatic charges repel and unlike charges attract each other. The electrical force of attraction or repulsion acting between two charged bodies is directly proportional to the product of the charges on the two bodies and inversely proportional to the square of the distance between them.

Induced Electrostatic Charges—It is possible for an electrically charged body to induce another electric charge in nearby bodies; that is, an apparently neutral body can be charged by bringing a charged body near to it, but not in contact with it. The induced charge is explained as the effect of attraction at a distance between, say, a positive charge, and the electrons in the initially uncharged body. The electrons are displaced slightly toward the inducing positive charge, making a negative charge at that end of the originally neutral body and leaving an equal positive charge at the opposite end; when the body inducing the charge is removed, the second body returns to its formerly neutral condition. This type of induced charge is called a **tempo-**

FIG. 2-15. Induced electrostatic charge.

rary induced electrostatic charge. As shown in Figure 2-15, if a positively charged rod is brought near an insulated metal sphere, a negative charge will be induced on the side of the sphere adjacent to the rod, and a positive charge will be induced on the opposite side. If the sphere is "grounded" by touching it on the positively charged side, electrons will flow from the positively charged rod holds the negative charge (electrons) bound on the opposite side. If first the finger, and then the rod, is removed, the sphere will be left with an excess of electrons, or a negative charge. This constitutes a **permanent induced electrostatic charge**.

Electric Discharge—If two bodies are in proximity to each other and one is electrified with a positive charge so as to be at a considerably higher potential than the other, it will, as described above, induce an opposite charge on the other body. It is possible to continue to increase the potential to a point where electrons will rush from the negatively-charged body across the intervening distance to the positively-charged body to balance the positive charge, thus causing a spark. The nature of the substance separating the two bodies determines how high a potential difference is necessary before transference of electrons can occur. Lightning results from a sudden discharge of a heavy charge of static electricity when, for example, a negatively charged cloud passes over the earth, inducing an op-

posite charge on objects below, such as trees and buildings. When these charges build up to a potential large enough to overcome the insulating resistance of the air, the air becomes a conductor and the excess electrons on the cloud rush to neutralize the positive charge below, the discharge spark being the familiar lightning flash. If the cloud is positively charged the flash will be upward, or if the induced charge is on another cloud the flash will occur between the clouds.

Static Electricity and Electricity in Motion—The electric current consists of electric charges in motion, as opposed to static electricity which consists of electric charges at rest. Some materials readily permit passage of the electric current and are known as **conductors**. Most metals are good conductors of electricity because of the "unbound" or "free" electrons characteristic of the outer shells of electrons of metallic atoms. Any electric potential will easily set in motion these electrons and a current will flow.

In other materials, the outer shells of electrons are bound more closely to the atom, and only very high potentials can cause transference of electrons from atom to atom to cause a flow of current. These latter materials are called **insulators**. Actually there is no sharp distinction between insulators and conductors, as materials merely differ enormously in conductivity.

When electric charges are added to or taken from insulators, or when electric charges move through conductors, experiment shows that it is generally the negative electrons that actually move. As soon as any movement of charges occurs, static electricity is immediately transformed into an **electric current** (electricity in motion).

It has been conventionally assumed that electric current flows from points of higher potential (+) to ones of lower potential (-). From the foregoing discussion, it is seen that electrical manifestations are due actually to flow of electrons from one point to another. The direction of flow of electrons, it is obvious, is opposite to the direction in which current has always been assumed to flow. It is necessary in discussing the flow of electric current to realize that although the current is assumed to flow from positive (+) to negative (-) it is the flow or drift of electrons from minus (-) to plus (+) that permits electrical forces to do useful work.

SECTION 6

CHEMICAL GENERATION OF ELECTRIC CURRENT

Since, in order to produce an electric current or flow of electricity, it is necessary to make electric charges move, a force called an **electromotive force** must be exerted on them. In electricity, this force is supplied by a **difference in potential, or voltage**; thus, there is a difference of potential between the two ends of a wire when there are forces present to make the charges in a wire flow as an electric current.

The simplest method of producing a difference in potential, and thus generating an electric current, is to use an **electric cell or storage battery** which converts chemical energy into electrical energy. Such a cell may consist of two dissimilar metals, such as zinc and copper, in the form of rods called **electrodes**, immersed in a bath of dilute sulphuric acid, which is called the **electrolyte**. The action of such a cell is as follows: zinc tends to go into solution as positively charged zinc atoms, or ions. Each positive zinc ion that goes into solution leaves a

corresponding excess negative charge on the zinc electrode. At the copper electrode, positive hydrogen ions from the dilute sulphuric acid (H_2SO_4) take electrons from the copper to form neutral hydrogen atoms. This leaves the copper electrode with a deficiency of electrons, that is, an excess positive charge. In this way, a potential difference is established between the two electrodes. However, there will be no flow of electric current until an external conducting wire is connected between the two electrodes; then, negative electrons flow through this conductor to the positive electrode or point of higher potential. Since the current generated by a battery always flows in only one direction (conventionally considered to be from the positive to the negative electrode), it is called **direct current**. Direct current can also be produced mechanically, as will be described later. As mentioned earlier, flow of electric current is conceived to take place from a point of higher

potential (+) to a point of lower potential (—). The conventional direction of current flow, therefore, is opposite to the direction of actual flow of electrons.

Only relatively small amounts of electricity can be

generated chemically, so devices called **generators** for producing electrical energy from mechanical energy have been developed; these are discussed in Section 12 under "Mechanical Generation of Electric Current."

SECTION 7

POTENTIAL, CURRENT, RESISTANCE

Potential—In order to move a charged particle (e.g., an electron) against an electrical force, work must be done on it. Consequently, potential energy must be added to it. If the particle is made to move from one point to another, the amount of potential energy (number of joules) added to the particle, per coulomb of charge on it, is called the potential difference between the two points. The common unit of potential difference is the volt. The volt is practically defined as that potential difference which will cause a current of one ampere to flow through a resistance of one ohm. The ampere and ohm are defined below. When an electrical force exists which is capable of moving a free positive charge from one point to another, the first point is said to be at a higher potential than the other, or it is said to be positive with respect to the other that is referred to as negative.

Current—When two ends of a wire conductor are connected to two points at different potentials, such as the terminals of a battery, an electric current flows in the wire. The mechanism of this current flow is roughly as follows. Initially, the conductor has equal numbers of positive and negative charges in its atoms. The atoms are packed together so closely that their electronic systems overlap to some extent, and it is comparatively easy for the outer electrons (referred to as "free" or "unbound" electrons) to pass from one atom to another when a small force is applied to them. The battery sets up a difference of potential between the ends of the wire and thus provides a force that causes the negative electrons in the wire to migrate from atom to atom toward the point of higher potential. This electron flow toward the positive terminal provides the actual means whereby electrical forces can be made to do useful work. It has been mentioned earlier that current flow has always been assumed as being from the point of higher potential (+) to the point of lower potential (—) or opposite to the electron flow. Materials differ considerably in the ease with which electrons can be made to migrate from atom to atom, or in other words, they differ considerably in electrical conductivity.

The magnitude of the current depends simply on the rate of flow of electrons through the conductor; that is, if each electron carries an electric charge, "e," the electric current, or rate of flow of electric charge, is determined by the net number of electrons per second carried through a section of the wire. If "n" electrons move through the wire each second, the charge moved per second will be "ne." The unit of current, the ampere, is legally defined as that unvarying current which when passed through a solution of silver nitrate (AgNO_3) in water in accordance with standard specifications will deposit silver at the rate of 0.001118 grams per second. It follows that, if the current is steady, the total charge passing through the section in a given time is merely the product of the current and the time. A coulomb is the quantity of electricity transferred when a current of one ampere flows for one second.

It is important to realize that steady electric currents ordinarily exist only in complete circuits, for such cur-

rents are simply the continuous circulation of electric charges; that is, the source of voltage circulates electric charges around through conductors like a pump circulates water. Furthermore, a steady electric current, like flow of water in a pipe, has the same value at all locations in a simple, unbranched circuit.

Resistance—The electric current in a conductor would be limited only by the number of available electrons, which is practically infinite, if it were not for the effect of electric resistance. This effect comes into play because the moving electrons do not pass freely and unhindered through the conductor, but collide with the atoms of the conductor and bounce off or trade places with electrons in the atoms. The resulting increase in the agitation of the atoms means an increase in heat energy. The greater the electric current, the greater the number of collisions, and the more electric energy is changed to heat energy. The electric current cannot exceed the value at which all electric energy becomes heat energy.

If the resistance of a conductor is increased, say by changing the material, the potential difference between the ends of the conductor needed to produce a given current will increase. The relationship between potential difference, current, and resistance is given by Ohm's Law, described in Section 8 immediately following. The unit of resistance is the ohm, which is the resistance of a column of mercury 106.3 centimeters in length, of uniform cross section and weighing 14.452 grams at 0° C.

The resistance of a wire is inversely proportional to the electrical conductivity of its material. As previously pointed out, materials differ considerably in conductivity. The resistance of a conductor depends on its size and shape as well as the nature of its material; thus, the larger the cross-sectional area of the conductor, the smaller its resistance, and the longer the conductor, the greater its resistance. In fact, the resistance of a conductor of uniform size and shape is directly proportional to the length and inversely proportional to the area; expressed mathematically,

$$R = R_s \frac{L}{A}$$

where "R" is the resistance of the conductor expressed in ohms, "L" is the length in meters or feet, "A" is the area in square millimeters or circular mils (area of a circle 1/1000 inch in diameter), and "R_s" is a proportionality factor or constant, called the **specific resistance** or **resistivity** of the material expressed in ohms per meter per square millimeter, or in ohms per circular mil per foot. Specific resistance or resistivity is merely the inverse of conductivity.

The resistance of metallic conductors usually increases as the temperature rises; for example, the resistance of pure metals increases by about 4 per cent for an increase of 18° F (10° C), whereas alloys usually have a smaller rate of change. In some alloys, the resistance remains practically constant over a wide range of temperature. The resistance of liquids, such as those

used in storage batteries, decreases as the temperature rises. If the temperature coefficient of resistance (α) of a material, and the resistance (R_0) of the material at

0°C , are known, the resistance at any other temperature (t) can be calculated from the equation, $R_t = R_0(1 + \alpha t)$.

SECTION 8

FLOW OF DIRECT CURRENT IN CONDUCTORS

Ohm's Law—The relationship between the difference of potential between two ends of a conductor and the current flowing in the conductor is given by Ohm's Law, which states that the current is directly proportional to the difference of potential or voltage; expressed mathematically,

$$V = RI$$

where "V" is the difference of potential in volts, "I" is the current in amperes, and "R" is the proportionality constant, the resistance, expressed in ohms.

Ohm's Law applies only to a uniform or steady current, that is, to a current of constant magnitude; it does not always hold for alternating current, such as is commonly used in lighting and power circuits (see section 13 of this part of Chapter 2: "Characteristics of Alternating Current"). Furthermore, the relationship is strictly true for metallic conductors only when there is no change in the temperature.

Resistance in Series—The preceding discussion of resistance has been limited to the flow of current through a very simple circuit, that is, through a conductor of uniform resistance connected to a storage battery. In practical circuits, it is customary to connect several different resistances together in the same complex circuits; in this case, the resistances may be coupled end to end in series, as shown in Figure 2-16, or in parallel, as

FIG. 2-16. Resistances in series. The combined resistance (R) is equal to the sum of individual resistances ($R_1 + R_2 + R_3$).

shown in Figure 2-17. When the resistances are connected in series, the total or combined resistance is equal to the sum of the individual resistances. Thus in Figure 2-16,

$$R = R_1 + R_2 + R_3$$

where "R" is the total resistance, and " R_1 ," " R_2 ," and " R_3 " are the individual resistances.

Resistances in Parallel—When the resistances are connected in parallel, as in Figure 2-17, the combined

FIG. 2-17. Resistances in parallel. The combined resistance (R) is less than any one of the individual resistances (R_1 , R_2 , or R_3).

resistance is less than the resistance of any one of them. This is apparent from the hydraulic analogue of this electric circuit, shown in Figure 2-18, consisting of

FIG. 2-18. Hydraulic analogue of electric resistance in parallel. Water mains (A and B) connected by small pipes (C and D) in parallel.

two large water mains connected by a single smaller pipe C. When the pipe D is added, another path is provided for the flow of water, hence more water will flow through the circuit and the total resistance to flow is decreased. The expression for computing the total resistance (R) of three resistances (R_1 , R_2 , R_3) in parallel is

$$\frac{1}{R} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3}$$

Law of Divided Circuits—When a current in a complex circuit divides, part flowing in one branch and part in another, the branch possessing the smaller resistance will conduct the larger part of the current. In fact, the ratio of currents in the two branches is inversely proportional to the ratio of the resistances of the branches. Thus in Figure 2-19,

$$\frac{I_1}{I_2} = \frac{R_2}{R_1}$$

where " I_1 " and " R_1 " represent the current and the resistance of one branch, and " I_2 " and " R_2 " the current and the resistance of the other branch.

FIG. 2-19. A divided circuit. The ratio of the currents (I_1 and I_2) in the two branches is inversely proportional to the ratio of the resistances (R_1 and R_2) of the branches.

Frequently it is desirable to have only part of a current flow through an instrument. For example, in order to measure a large current with a galvanometer or ammeter, which is not capable of carrying the whole current, a conductor may be connected across the terminals of the instrument so that the current will divide, part going through the instrument and part through the conductor of known, calibrated resistance. A conductor used in this way is called a **shunt**.

SECTION 9

ELECTROMAGNETISM

Magnetic Fields and Electric Currents—There is an important connection between magnetism and electricity which is that a magnetic field is produced around a wire carrying an electric current. This can be demonstrated by the deflection of a compass needle (magnet) when it is brought near a vertical wire carrying a current, or by the positions assumed by iron filings in concentric circles around the wire on a plane (sheet of paper) perpendicular to the wire, as indicated in Figure 2--20. The lines of force are circular and lie in planes

FIG. 2--20. Magnetic field about a wire carrying a current, shown by iron filings on a sheet of paper.

perpendicular to the current. The direction of the magnetic field with respect to the direction of the current is given by the **right-hand rule**; that is, if the wire is grasped in the right hand, so that the thumb points in the direction of the current, the fingers will point around the wire in the direction of the magnetic field. The strength of the field is directly proportional to the current in the wire.

This same rule applies even though the wire may be bent into a loop (Figure 2--21). When several loops of

FIG. 2--21. Magnetic field about a single loop of wire carrying a current.

wire are wound to form a coil, most of the magnetic lines will pass through the entire coil (Figure 2--22). Such a loose coil of wire is known as an **air-core solenoid**. If now, an iron core is placed within the coil to

FIG. 2--22. Magnetic field about a solenoid carrying a current

form an **iron-core solenoid**, the strength of the magnetic field about the coil is increased tremendously. The reason for this is that when the iron core becomes magnetized, the field of force of the magnet lines up with the field of the coil to produce an intense magnetic field. This arrangement consisting of an iron core in a helical wire coil (Figure 2--23) is commonly called an **electromagnet**.

FIG. 2--23. Solenoid with iron core, showing concentration of magnetic flux.

The strength of the magnetic field within a large solenoid or coil with an air core is given by:

$$H = \frac{4\pi NI}{10}$$

where "H" is the field strength in gauss, "N" is the number of turns of wire in the coil per centimeter of coil length, and "I" is the current in the wire in amperes. The field strength of an electromagnet can be calculated from this expression: in practice, the strength of electromagnets is rated in terms of **ampere-turns** (product of the current in amperes times the number of turns of wire in the coil— IN). When the coil contains an iron

core, which is more permeable than air, the same number of ampere turns in the coil will yield a much greater field strength as mentioned above. The exact amount of the increase in field strength will depend on the permeability of the iron core—the higher the permeability of the iron core the greater the increase in field strength over that of the coil alone.

The permeability of iron may vary considerably, depending upon its purity, microstructure, and state of internal stress. In fact, the relationship between the magnetizing force of the wire coil alone, and the strength of the induced magnetic field when the iron core is inserted is given by:

$$B = \mu H$$

where "H" is the magnetizing force of the coil alone in gauss, "B" is the strength of the induced magnetic field when the core is inserted, and " μ " is the permeability of the iron. If the value for the field strength "H" given above is inserted in this expression:

$$B = \frac{4 \pi \mu NI}{10}$$

The value of " μ " is not constant but varies with the magnetizing force "H," as shown by the typical curve of Figure 2-24. The field strength of the electromagnet

FIG. 2-24. A typical magnetization curve for iron.

can be increased still further by providing a more complete iron circuit so that the magnetic lines of force travel largely through the iron, that is, by extending the iron core outside of the coil until its two ends nearly meet in the shape of a C.

FIG. 2-25. Force on a wire suspended in a strong magnetic field.

Another equally important aspect of the relationship between electric currents and magnetic fields is that a wire carrying a current experiences a mechanical force when placed in a magnetic field. If a wire carrying a current is loosely suspended in a strong magnetic field, the wire will tend to move in the direction indicated in Figure 2-25; if the direction of the current in the wire is reversed by changing the battery connections, the wire will move in the opposite direction. It will be noted that, in either case, the force on the wire is perpendicular to both the magnetic field and to the current. This mutual perpendicularity between the three directions of force, field, and current is characteristic of relationships between mechanical, magnetic, and electrical phenomena. The magnitude of the force depends on the current, the strength of the magnetic field, and on the length of the wire in the field; that is, the force is proportional to the current times the magnetic field strength times the length of the wire. Since the force, current, and length can be readily measured, it is convenient to define the unit of magnetic field strength in these terms.

If a single loop of wire is suspended between the poles of a magnet, and a current is produced in the wire loop, as in Figure 2-26, the direction of the current in the

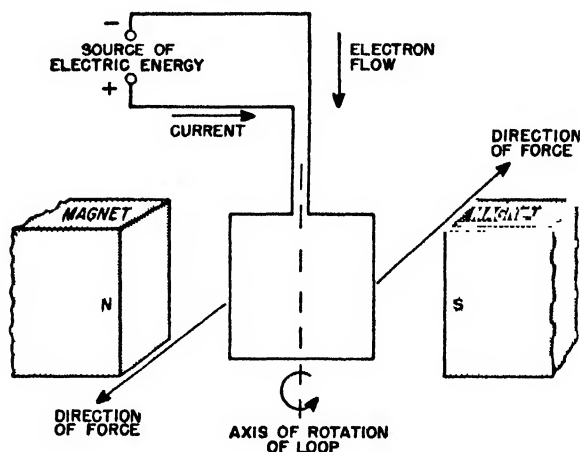

FIG. 2-26. Loop of wire carrying a current and suspended in a strong magnetic field. Forces tend to cause rotation.

left-hand part of the loop is such that the force is directed toward the reader, whereas in the right-hand part, the current is opposite, so the force is directed away from the reader. These equal and opposite forces tend to make the wire loop rotate. The effectiveness of the forces tending to produce this twist is called the torque, and in this case it is the product of one force and the distance between the two forces. The tendency of a loop of wire carrying a current to rotate in a magnetic field is the basis for electric motors which transform electric energy into mechanical energy (see Section 14). Conversely, if a wire carrying no current originally is moved through a magnetic field so as to cut the lines of force of the field, an electric current will flow through the wire; this principle is employed in generators converting mechanical energy into electrical energy, as discussed in Section 12.

SECTION 10

ELECTRIC ENERGY AND POWER

Energy—Electric energy is determined in much the same way as is mechanical potential energy. The potential energy that is changed to other forms of energy when a body of weight "W" and mass "m" falls through a distance "h" is given by the expression:

Potential Energy = $Wh = mgh$ (foot-pounds or joules)

Similarly, the electric energy that is changed to other forms when an electric charge "Q" falls through a difference of potential "V" is given by:

Electric Energy = QV (joules)

In practice, the charge "Q" is not measured directly, instead the current "I," which is the rate of flow of electric charge, is measured, and the total charge passing through a section of the circuit in time "t" is obtained from the relation

$$Q = It$$

which is true if "I" does not change. If "V" is also constant, the quantity "It" can be substituted for "Q" in the expression for electric energy:

Electric Energy = VIt (joules)

Inasmuch as electric energy is readily transformed into heat energy in resistances, it is often desirable to know the amount of heat energy generated when a steady current "I" flows in a resistance "R" for time "t." The electric energy transformed into heat energy is:

$$VIt = I^2Rt \text{ (joules)}$$

since the potential difference "V" between the two ends of a resistance is equal to "IR" volts.

It has been pointed out earlier that the mechanical equivalent of heat is given by

$$\begin{aligned} 4,186 \text{ joules} &= 1 \text{ calorie} \\ \text{or } 4,186 \text{ joules} &= 1 \text{ kilocalorie} \end{aligned}$$

Therefore, the above equation for electric energy transformed into heat energy may also be written:

$$\begin{aligned} VIt &= \frac{RI^2t}{4,186} \text{ (kilocalories)} \\ &= 0.00024 RI^2t \text{ (kilocalories)} \end{aligned}$$

Power—Frequently it is desirable to know how much energy is being generated or consumed per unit time rather than the total energy, in other words, to know the power of a generator or motor.

From the above discussion on electric energy, it is apparent that, if "V" and "I" are constant,

$$\text{Power} = \frac{\text{energy}}{\text{time}} = VI \text{ (joules per second or watts)}$$

The unit of electric power is the watt; since this unit is very small compared to the power generated and used today, a larger or multiple of this unit, called the kilowatt, is generally used (1 kilowatt = 1000 watts).

There are several ways of expressing electric power in terms of resistance, current, and potential difference. Since $V = IR$, then

$$\text{Power} = VI = I^2R = \frac{V^2}{R} \text{ (watts)}$$

In a simple circuit, the power dissipated in a resistance can be determined by measuring the two quantities in any one of these expressions.

SECTION 11

ELECTROMAGNETIC INDUCTION

If a coil of wire is connected to a galvanometer and a magnet is pushed into the coil, the galvanometer pointer momentarily deflects, indicating a current, but it returns quickly to zero when the magnet is held stationary within the coil. When the magnet is pulled out of the coil, the pointer deflects in the opposite direction, but again becomes zero almost immediately. It may be concluded then that only moving or changing magnetic fields induce electric currents, as no current is generated in the coil when the magnet is at rest. Evidently, either the magnet or the coil can be moved in order to produce a current. Thus mechanical energy can be converted into electric energy by moving a coil and a magnet with respect to each other.

A current can also be produced by means of two coils, instead of a magnet and a coil (Figure 2-27). When a current is produced in the first coil, a magnetic field quickly radiates from this coil and its lines of force spread out and cross the wires in the second coil nearby. This electromagnetic disturbance induces a momentary current in the second coil. The pointer of a galvanometer connected to the second coil deflects momentarily and then returns quickly to zero. However, no current flows in the second coil as long as the current in the first coil is steady. When the current in the first coil is stopped, by opening a switch, again there is a momentary current

in the second coil, but in the opposite direction. Evidently, current is induced only when the current in the first coil is changing; that is, when the magnetic field produced by it is changing. By reversing the direction of the applied current, or by turning one of the coils end for end, the direction of the induced current indicated by the galvanometer is reversed. Thus, the second coil must be subjected to a changing magnetic field if cur-

FIG. 2-27. Changing current in coil A induces a current in coil B.

rents are to be induced in it. The changing field, therefore, can be produced either by varying the current in a nearby stationary coil, or by actually moving the first and second coils with respect to each other. If this experiment is repeated with the two coils placed on a single iron core, the induced current in the second coil is greatly increased, because iron greatly increases the magnetic field produced by the current in the first coil and tends to lead the lines of force from the first coil through the second.

Self-Induction—Whenever the current in a solenoid changes, the lines of flux cut every turn within the solenoid itself and induce within the coil a voltage opposing or counter to the change. This phenomenon is known as **self-induction**. As the current decreases, there is a forward voltage or electromotive force (e.m.f.); as it increases there is a back electromotive force. Thus, the induced electromotive force tends to keep the current

unchanged. This is analogous to the action of mass in mechanics and may be thought of as electrical inertia. The measure of self-induction is the **coefficient of self-induction** or **self-inductance** (L).

Laws of Electromagnetic Induction—From experiments such as those described above, the following laws pertaining to electromagnetic induction can be deduced:

1. Any change in the number of lines of force passing through a closed conducting circuit induces a current in that circuit.
2. The direction of the induced current is always such that its magnetic field opposes the motion which produces it (**Lenz's Law**).
3. The electromotive force of the induced current is directly proportional to the rate at which the number of lines of force are increased or decreased, or to the rate at which the lines of force are cut.

SECTION 12

MECHANICAL GENERATION OF ELECTRIC CURRENT

Alternating-Current Generator—If a single loop of wire is placed in a strong magnetic field and is rotated by means of a torque applied to it with a crank or pulley (Figure 2—28), the wire on the left moves in one direction through the magnetic field, and the wire on the right moves in the opposite direction. Therefore, the voltages induced in both wires set up a current in the same direction in the loop. However, as the loop is rotated a half revolution further, the two wires ex-

change directions through the magnetic field, so that the induced voltages are opposite to the previous ones, and the current flows in the opposite direction through the loop.

The change in total voltage during one complete rotation of the loop is represented graphically in Figure 2—28. The voltage increases from zero at position "P" to a maximum in one direction, called positive, as the wires pass one pair of poles and then decreases to zero a half revolution from position "P." As the loop is rotated further and the wires pass the opposite pair of poles, the voltage reverses and becomes a maximum in the opposite direction, called negative; it then decreases to zero again as the loop returns to position "P." This type of device produces an alternating positive and negative voltage, resulting in a current first in one direction and then in the opposite direction, and therefore is called an **alternating-current (AC) generator**. The number of complete reversals or cycles of voltage per second is termed the **frequency** of oscillation of the voltage. This type of generator, in a more complex form, is in many ways more useful than one which produces a voltage, and therefore a current, always in the same direction.

Direct-Current Generator—In order to obtain voltage and current from a generator in one direction only, a commutator-brush switching arrangement must be introduced. Such an arrangement illustrated in Figure 2—29 reverses the connections to the armature at the proper times, so that the current will always be in the same direction. By providing several armature coils of many turns of wire on an iron core and connecting them to commutator segments, and by using electromagnets to supply the fixed magnetic field, a relatively steady **direct current** can be produced when the armature is rotated.

FIG. 2—28. Change in voltage induced in a wire loop during one complete rotation in a magnetic field.

SECTION 13

CHARACTERISTICS OF ALTERNATING CURRENT

The flow of alternating current is different in many respects from that of direct current—many new phenomena appear. For example, when two alternating cur-

rents are fed into a conductor, the resulting current may be anything from zero to the sum of the two, depending on their relative phases. Furthermore, the voltage may

be out of phase with the current, so that although there may be both current and voltage, there may be no power. Also, alternating current can flow where direct current cannot and vice versa.

Frequency—In the discussion of the simple two-pole alternating generator, it was pointed out that the generated voltage fluctuates from zero to a maximum in the positive direction, back to zero, then to a maximum in the negative direction, and finally back to zero, during one revolution of the armature. This complete reversal of voltage, consisting of two alternations, is called a cycle. If the armature rotates 60 revolutions every second, the frequency of the resulting voltage is 60 cycles per second, the most commonly used frequency. In practice, to avoid the necessity of running a generator at such a high speed, several pairs of poles are arranged in a circle around the armature, so that north and south poles alternate in position. If there are 10 poles (5 pairs), 5 cycles will be generated per revolution, and the generator can be run at 12 revolutions per second, or 720 revolutions per minute, in order to produce 60-cycle current.

It should be pointed out that the alternating current fluctuates in a systematic way (sinusoidal wave form) just as does the voltage. When alternating current flows through a simple resistance, the voltage and current waves are in step (phase) and are represented together as a single wave; that is, the voltage is greatest at the same time that the current is greatest. Under certain conditions, however, the voltage may not be in phase with the current, and this situation is represented by two waves, one displaced along the time axis with respect to the other.

Polyphase Current—In the simple alternating-current generator possessing a loop or two coils in the armature, described previously, much of the space in the magnetic field is wasted. This space can be utilized by placing additional pairs of coils in the armature; thus, if a second pair of coils is added, a second independent current supply is provided. The voltage generated in these coils is just 90 degrees out of phase with that of the first pair of coils, because the magnetic flux through this second pair of coils is a maximum when that through the other pair is zero; this is a **two-phase generator**. Frequently three such sets of independent circuits are employed in the armature to produce **three-phase current**.

Effective Values of Alternating Current and Voltage—It is not possible to use the average value of the alternating current sine wave as a measure of current, be-

cause this value is zero. However, the energy delivered, or heat developed, is equal to I^2R , the value of I^2 , though varying, is always positive. Therefore, the square root of the average value of I^2 may be taken as the effective value (I_e) of alternating current (root mean square current). The effective value of AC voltage (V_e) has the same meaning. The root mean square values are approximately seven-tenths of the maximum values for the currents and voltages. It is these effective values which are read directly on AC ammeters and voltmeters.

Impedance—When alternating current flows through a simple resistance, the relation between current and voltage is given by Ohm's Law,

$$I_e = \frac{V_e}{R}$$

but, in general, Ohm's Law cannot be used for alternating current. Alternating current differs from direct current in at least two important respects; that is, alternating current is impeded by the self-induction of a coil, whereas direct current flows unhindered, and alternating current effectively passes through a capacitor according to an appropriate impedance, whereas direct current cannot flow at all. For alternating current, it is necessary, therefore, to introduce a new property of a circuit, called impedance (Z), to replace the term resistance in Ohm's Law:

$$I_e = \frac{V_e}{Z}$$

The impedance (Z) includes a resistance term and a reactance term. This latter term is frequency dependent and is actually composed of two terms, the inductive reactance and the capacitive reactance. The mathematical expression for the impedance Z is:

$$Z = \sqrt{R^2 + \left(2\pi fL - \frac{1}{2\pi fC}\right)^2}$$

Power Factor—Any self-induction in a circuit causes a difference in phase between the voltage and the current, so that the current either forges ahead or lags behind the voltage, and the two do not reach their maxima and minima together. Consequently, at any instant the product of the voltage and current, which represents the energy available for use, is less than the total energy supplied to the circuit. The ratio, expressed in per cent, between the useful voltage that is available for overcoming resistance of conductors, to produce heat, or to run a motor, and the actual or measured voltage, is called the **power factor**.

SECTION 14

PRINCIPLES OF MOTORS

In rotating the armature of a generator, mechanical energy is converted into electrical energy, whereas in operating a motor, electric energy is converted into mechanical energy, so that the motor and the generator perform operations which are the converse of one another. The amount of electric energy generated is never quite equal to the mechanical energy input and vice versa, because a certain small amount of mechanical energy is dissipated as mechanical friction and heat in the generator or motor. In many respects, a generator is like a water pump in that it forces electrons to circulate through wires to electrical machines or appliances, where they do useful work and then return to the generator.

Direct-Current Motor—In order to make a loop or coil of wire, suspended between the poles of a magnet, rotate continuously when a direct current is passed through the wire, a switching arrangement, called a **commutator**, must be provided, so that the current through the coil is reversed in direction just as the coil aligns itself with the fixed field magnetic poles. The coil is then magnetized in such a way that it must rotate still further to line up in the opposite position. This process is repeated indefinitely, producing a continuous rotation of the armature coil. The coil is always reversed at just the proper time to carry on the rotation of the coil. The commutator consists of two copper segments insulated from each other and connected to the ends of the coil.

The current is carried to the commutator segments by carbon contacts called "brushes" which are forced by springs to rub against successive commutator segments. This simple motor arrangement is shown diagrammatically in Figure 2-29.

FIG. 2-29. Principle of direct-current motor. The commutator consists of two metal segments (C) separated by an insulator (I).

In practice, the armature consists of several coils of many turns of wire wound on an iron core to provide large magnetic forces. Also, the fixed magnetic field is usually produced by sending some of the current from the source of electric energy into field coils wound on iron cores, instead of by means of permanent magnets. When the field coils are placed in parallel with the armature coils, as in Figure 2-30, the motor is called a **shunt motor**. This is the usual connection for large direct-current motors. When the field coils are connected in series with the armature coils, the motor is called a **series motor** (Figure 2-31). Most small motors are of the latter type and can be used on either direct current or alternating current. Another type of direct-current motor combines some of the advantages of the series and shunt windings; this is the **compound-wound motor** (Figure 2-32).

Alternating-Current Motor—Inasmuch as alternating current is more conveniently transmitted than direct current, motors have been developed especially for operation by power from this source. Alternating-current motors are simpler in construction than direct-current motors. Thus, in Figure 2-33 a closed wire loop is shown suspended between the poles of an electromagnet which has alternating current applied to it. The current in the loop is induced by an increase in the magnetic field, caused by an increase in voltage and current in the electromagnet windings. If the magnetic field then starts to decrease, as the coil rotates 90 degrees past the first position, the direction of the induced current in the loop will reverse, and the mechanical forces will be such that the rotation continues indefinitely in the same direction. The number of revolutions per second will be equal to the alternating-current frequency in cycles per second. It is evident, therefore, that the main differences between an alternating-current motor and a direct-current motor are: the

FIG. 2-30. Simple shunt-wound direct-current motor.

FIG. 2-31. Simple series-wound direct-current motor.

FIG. 2-32. Simple compound-wound direct-current motor

FIG. 2-33. Principle of alternating-current induction motor.

armature current is induced instead of being supplied to the armature through brushes, the direction of the induced current is reversed automatically twice during each alternating-current cycle in the electromagnetic

windings, so that the need for a commutator is eliminated, and the speed of rotation is controlled by the alternating-current frequency. Further discussion of alternating-current motors will be found in Chapter 24.

SECTION 15

PRINCIPLES OF TRANSFORMERS

If two coils of wire are wound on an iron core, and one coil, called the **primary**, is connected to a source of 60-cycle alternating current, such as an AC generator, the voltage across the primary coil will increase from zero to a maximum value in the positive direction in $\frac{1}{240}$ second, return to zero in the next $\frac{1}{240}$ second, increase again to a maximum but in the negative direction in the third $\frac{1}{240}$ second, and will finally return to zero in the fourth $\frac{1}{240}$ second. The current fluctuates in a similar manner following the voltage, continuously repeating the cycle every $\frac{1}{60}$ second. As the current in the primary coil reverses direction twice each cycle or $\frac{1}{60}$ second, the magnetic field accompanying this changing current sweeps back and forth across the other coil, called the **secondary** coil, at the same rate. This fluctuating magnetic field induces an alternating voltage in the secondary coil, even though there is no direct connection between the two coils. A device of this kind is known as a **transformer** (Figure 2-34). Transformers

in the secondary coil as in the primary. In general, the ratio of the voltage across the primary (V_1) to that across the secondary (V_2) is the same as the ratio of the number of turns in the primary (N_1) to that in the secondary (N_2), or expressed mathematically:

$$\frac{V_2}{V_1} = \frac{N_2}{N_1}$$

Accompanying this change in voltage there is a change in the current, but in the inverse ratio; that is, if the voltage is stepped up 100 times in the secondary, the current will be reduced about 100 times. In general, for a transformer, the product of the voltage (V_1) and current (I_1) in the primary is equal to the product of the voltage (V_2) and current (I_2) in the secondary; expressed mathematically:

$$\frac{V_1}{V_2} = \frac{I_2}{I_1}$$

FIG. 2-34. Simple step-up transformer.

will not operate on continuous direct current, because no induced current can be produced by a steady direct current. For this reason they are nearly always operated on alternating current because it is simpler to use AC than to provide an interrupted direct current. The iron core serves, as in an electromagnet or armature, to guide the magnetic field from one coil through the other. In practice this iron core is laminated; that is, it is made up of several thin iron strips, which arrangement increases the resistance of the core to the flow of parasitic or eddy currents that tend to cause heating of the core and reduce the efficiency of the transformer.

The transformer is important because of its ability to "step up" or "step down" the voltage from a given source. If a voltage 100 times greater than that available is required, it is merely necessary to provide 100 times as many turns in the secondary as in the primary; on the other hand, if a voltage of $\frac{1}{100}$ of that available is needed, it may be obtained by using $\frac{1}{100}$ as many turns

Even though a voltage is induced in the secondary, there is no current whatever in the secondary until it is connected to some device that completes the circuit. Furthermore, the current in the primary is nearly zero if there is no current in the secondary. When current flows in the secondary, the primary current increases correspondingly, so that the electric power output and input are always in balance. Thus, the transformer is a kind of self-adjusting device.

In transmitting electric energy through wires over long distances, it is customary to employ high voltages and low currents, rather than low voltages and high currents; the reason for this is that in low-voltage, high-current transmission, over a long length of wire, the voltage drop (IR) is large, and even worse, the power loss (I^2R) is very great. Thus, step-up transformers are employed to raise the voltage from alternating-current generators, which is usually 120 to 3,000 volts, up to voltages of 12,000 to 120,000 for transmission. At the place where the electric energy is to be used, the voltage must then be reduced again, by means of a step-down transformer, to voltages of 110 or 240, in order to operate ordinary motors, lights, and appliances. A modern high-voltage, low-current transmission line is shown schematically in Figure 2-35.

FIG. 2-35. High-voltage, low-current transmission system.

SECTION 16

CURRENT RECTIFICATION

Since, for economic reasons, alternating current is almost universally used for transmission and distribution, some method must be available to change it into direct current when the latter is more desirable for industrial use. The two principal types of equipment used for changing large amounts of alternating-current power to direct-current power in the steel industry are motor-generator sets and rectifiers.

Motor-Generator Sets—The simplest form of motor-generator set consists of an alternating-current motor and a direct-current generator. In practice, several direct-current generators may be operated by one alternating-current motor. Each of the generators can be designed so that the voltage at which the direct current is delivered is different for each generator.

Frequency Changers—Motor-generator sets are not always built for the purpose of changing alternating current into direct current. Sixty cycles per minute is the most commonly used frequency in this country. However, in some sections of the country, industry requires alternating current at the frequency of 25 cycles for use in motor drives. A special type of motor-generator set, called a **frequency changer** is employed for this purpose. The alternating-current motor for such a set is designed for the frequency at which the power is delivered and the generator is designed to deliver alternating current of the desired frequency.

Mercury-Arc Rectifiers—For changing large amounts of alternating-current power to direct-current power, an electronic type of rectifier more commonly known as the mercury-arc rectifier is employed in steel-plant service. The principle of operation of a mercury-arc rectifier is illustrated schematically in Figure 2-36. A rectifier may be described as a device which will permit current to pass through it in only one direction. Thus, when alternating current is applied, current passes through the rectifier during the positive half cycles, but not during the negative half cycles. If single-

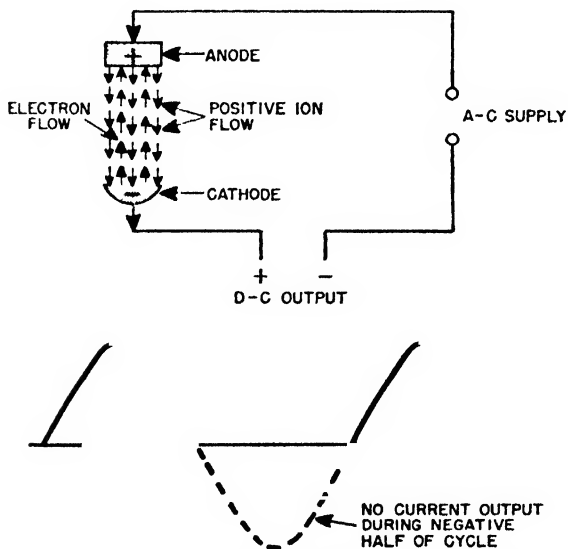

FIG. 2-36. Principle of operation of all electronic rectifiers. With this simple arrangement, half-wave rectification occurs. (Courtesy, "Iron and Steel Engineer.")

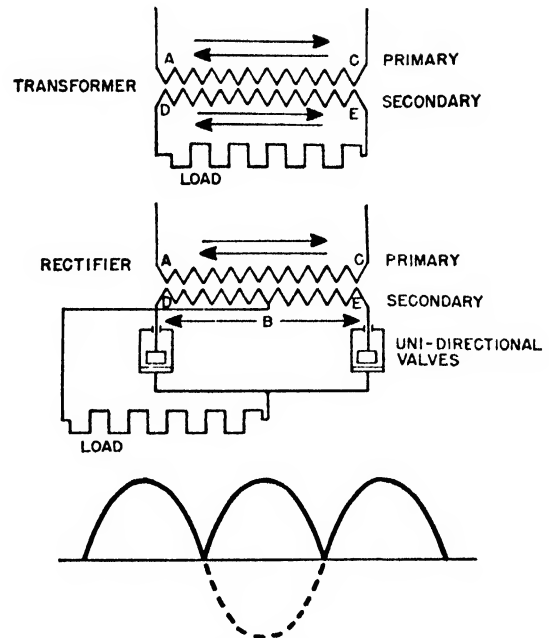

FIG. 2-37. Diagram of single phase mercury arc rectifier arrangement to provide full-wave rectification. (Courtesy, "Iron and Steel Engineer.")

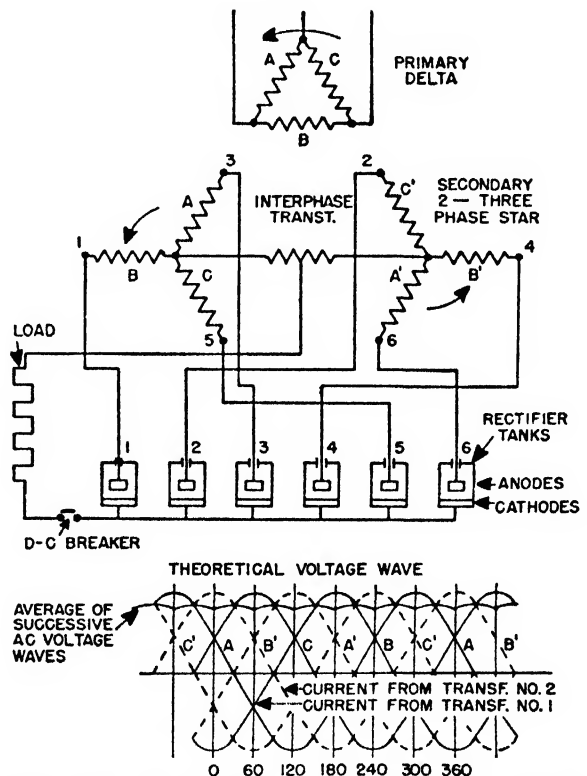

FIG. 2-38. Diagram of six phase ignitron or excitron type mercury arc rectifier. (Courtesy, "Iron and Steel Engineer.")

phase alternating current is rectified in this manner, half-wave rectification results, as indicated at the bottom of the illustration.

All electronic rectifiers depend upon a flow of electrons from cathode to anode. This flow will not start until the anode is positively charged with respect to the cathode. Once started, the flow of electrons continues until the anode becomes negative with respect to the cathode. This happens at the end of each positive half cycle. Mercury vapor from the pool that serves as a cathode provides the conducting medium for the arc through which the current flows.

The mercury-arc rectifier depends for the start and continuation of electron flow upon the ignition and maintenance of a hot spot upon the cathode each positive half cycle. This hot spot provides the necessary vaporization of mercury.

The simplest practical form of full-wave rectification consists of a single-phase transformer with a rectifying element in each leg of the secondary circuit. The return circuit is connected to the mid-point of the transformer winding (Figure 2—37). As the current in the primary of the transformer flows from left to right, a voltage is

set up in the secondary from right to left. The mercury-arc rectifier in the left-hand leg of the secondary permits flow of current in one direction only, so that the current flows through that rectifier, through the load circuit, and back to the neutral connection in the secondary. When the direction of current is reversed in the primary of the transformer, the flow of current in the transformer secondary is through the right-hand half of the secondary winding, through the rectifier at the right, through the load circuit, and back to the neutral connection of the secondary. The rectified voltage is always positive, varying from zero to a maximum positive value for each half cycle. The dotted line indicates how the voltage would have changed from positive to negative if rectification were not employed.

In order to obtain large power capacities for practical use, it is necessary to obtain direct-current voltages of a more uniform value than can be obtained by single-phase rectification. To obtain this result, a six or more phase rectifier is normally used (Figure 2—38). By this means, the voltage never falls outside of set limits and never becomes zero, so that a satisfactorily steady direct current is delivered to the load circuit.

Chapter 3

FUELS AND COMBUSTION

SECTION 1

INTRODUCTORY

Any substance capable of producing heat by combustion may be termed a **fuel**. However, it is customary to rank as fuels only those which include carbon and hydrogen and their compounds. Wood was the earliest fuel used by man. Coal was known to exist in the fourth century B.C., and petroleum was used by the Persians in the days of Alexander. Prehistoric records of China and Japan are said to contain references to the use of natural gas for lighting and heating.

Heat generated by the combustion of fuel is utilized in industry directly as heat or is converted into mechanical or electrical energy. Fuel has become the major source of energy for manufacturing enterprises. In America, fuel has been produced and exploited to a greater extent than in any other country. The United States became the leading coal-producing country of the world in 1889, and in 1902 took the lead in crude-petroleum production from Russia. The United States is also the leading producer of natural gas.

Fuel enters significantly into manufacturing costs, as it generally represents one of the four largest items of expense. In some industries it is the largest. The steel industry is one of the three major consumers of coal but, since coal is used so universally, consumes only about 15 per cent of the total produced. In periods of high pro-

duction, the steel industry expends annually over a quarter of a billion dollars for coal. A modern fully-integrated steel plant consumes approximately a ton of coal for each ton of steel ingots produced. The steel industry also consumes large quantities of natural gas and petroleum. A comparison of petroleum consumption in the steel industry to total production is not so significant as with coal. However, some steel plants rely on oil as their major fuel.

The enormous annual consumption of coal, petroleum, and natural gas in the United States has provoked interest in the natural resources of these materials. Our known resources are still the greatest in the world, but the best and most readily accessible petroleum and natural gas are said, by some authorities, to approach depletion, at the present high rates of consumption, before 2000 A.D. However, when the less desirable coal beds are included, the known coal reserves have been estimated to be sufficient to last anywhere from three hundred to two thousand years. Some industries are developing synthetic fuels, particularly liquid and gaseous fuels from lower-grade coal, in anticipation of the time when their use will be justified economically. Efficient fuel utilization has been intensified not only by the prospect of depletion, but also by rising costs of fuel production.

SECTION 2

CLASSIFICATION OF FUELS

The Classification of Fuels—Fuels are classified usually into three general divisions; viz., **solid**, **liquid**, and **gaseous**. Fuels in each general division can be classified further as **natural**, **manufactured**, or **by-product**. Fuels found in nature sometimes are called **primary fuels**; those manufactured for a specific purpose or market, together with those which are the unavoidable by-product of some regular manufacturing process, are called **secondary fuels**. The primary fuels serve as the principal raw materials for the secondary fuels. Table 3—I gives a classified list of the important fuels. It also lists some interesting by-product fuels, many of which have been utilized by industry to conserve primary fuel.

Importance of Each Class—Although there has been a decline in the use of coal, and a proportional increase in petroleum and natural gas consumption, it is improbable that either of the latter two fuels, because of the great difference in reserves, will ever surpass coal as an industrial fuel, unless they are made synthetically from coal. Coal is the major fuel of public utilities for the generation of power and is essential to the steel industry for

the manufacture of coke. It has been supplanted to a large extent by liquid fuels for the generation of motive power by railroads. It is a major raw material in many chemical plants as a source of carbon, hydrogen, and their compounds. Industrial coal consumption is about five times that of household.

The growth of petroleum consumption has been phenomenal in the past forty years due to the increasing demand for its distillation products. Gasoline, the most important product, is used as a motor fuel. Light oil is used for Diesel engines. Distillate and residual fuel oils, and some crude petroleum of too low commercial value for distillation, are used for industrial and domestic heating. Crude and refined petroleum of various grades is used for lubrication of all types of machinery and prime movers. Petroleum is the base for many synthetic products and is competitive with coal chemicals in a number of important applications.

The marketed production of natural gas increased fourfold in the twenty years prior to 1945, and the quantity used in that year was approximately 165,000,000 tons

Table 3—I. Classification of Fuels

General Division	Primary Fuels	Secondary Fuels	
	Natural	Manufactured	By-Product
Solid	Anthracite coal Bituminous coal Lignite Peat Wood	Semi-coke (low temperature coal distillate)	Charcoal—low temperature distillation of wood
		Coke Charcoal Briquettes { Coal slack and culm Lignite Peat Sawdust Petroleum residue Pulverized coal	Wood refuse—shavings, trimmings, tan bark, sawdust, etc. Bagasse—refuse sugar cane Anthracite culm—silt refuse of anthracite screening Coke Breeze { By-product coke—screenings Petroleum coke—petroleum residue Waste Materials { Corn from Grain { Barley Wheat Buckwheat Sorghum
Liquid	Petroleum	Gasoline Kerosene Alcohol Colloidal fuels Fuel oil { Residual oils Distillate oils Crude petroleum Naphtha Vegetable oils { Palm Cottonseed	Coal distillates { Tar Naphthalene } coke manu- Pitch facture Benzol Acid sludge—petroleum refining residue Pulp mill waste
Gaseous	Natural Gas	Producer gas Water gas Carburetted water gas Coal gas Oil gas Reformed natural gas Butane ^(a) Propane ^(a) Acetylene Hydrogen	Blast furnace gas—pig iron manufacture Coke oven gas ^(b) —coke manufacture Oil refinery gas Sewage gas—sewage sludge

^(a)Liquefiable heavier constituents of natural gas.

^(b)Considered by-product of coke manufacture in steel industry but a manufactured fuel in the gas industry. Gas industry produced 45 billion cubic feet of coke-oven gas and purchased 93 billion cubic feet (a total of 138 billion cubic feet) for sale in 1952, of a total national production of 923 billion cubic feet. (Based on figures from "Gas Facts," American Gas Association, 1952 Data; and "Mineral Industry Surveys," U. S. Dept. of the Interior, Bureau of Mines, July 1953.)

of coal equivalent, equal to about one-third the annual production of coal. During 1950, marketed production of natural gas was estimated to have increased 16 per cent to 6,281 billion cubic feet (263,800,000 tons of coal equivalent), the largest annual increase in quantity and percentage of the previous decade. Natural gas has replaced coal to a considerable extent for domestic and industrial

heating due to the installation of very large pipe lines from producing to consuming centers, the rise in the price of solid fuel, the relative level in the price of natural gas over the intervening time, and its convenience, cleanliness, controllability and versatility as a fuel. The by-product gaseous fuels—coke-oven gas and blast-furnace gas—are major iron and steel industry fuels.

SECTION 3

PRINCIPLES OF COMBUSTION

Fuels consist essentially of one, or a mixture of two or more, of four combustible constituents: (1) solid carbon, (2) hydrocarbons, (3) carbon monoxide, and (4) hydrogen. In addition to these combustible constituents, nearly all commercial fuels contain inert material, such as ash, nitrogen, carbon dioxide, and water. Bituminous coal is an example of a fuel which contains all four of the combustible constituents named above, and coke is an example of a fuel containing only one (solid carbon). The constituents which make up liquid

fuels and many coals are quite complex, but since these complex constituents decompose or volatilize into the four simpler constituents named above before actual combustion takes place, a knowledge of the combustion characteristics of these constituents is sufficient for nearly all practical applications. All of these four constituents of fuels except carbon are gases at the temperatures where combustion occurs. Combustion takes place by combining oxygen, a gas present in air, with the combustible constituents of a fuel. The complete combustion

of all fuels generates gases. It is apparent, therefore, that a review of the properties, thermal values and chemical reactions of gases is necessary for an understanding of any class of fuel.

Since fuels are used to develop heat, a knowledge of heat terms and the principles of heat flow are essential for the efficient utilization of this heat. The combustion of fuels involves, besides combustion reactions, the factors and principles which influence speed of combustion, ignition temperature, flame luminosity, flame development, flame temperature and limits of flammability. The ensuing divisions of this section deal generally with these subjects. Sections 5, 6 and 7, respectively, deal specifically with the combustion of solid, liquid and gaseous fuels.

Calorific Value of Fuels—Heat is measured under the English system in terms of **British thermal units (Btu)**; under the metric system the corresponding unit is the **caloric**. A **Btu** is defined as 1/180 of the amount of heat required to raise the temperature of a pound of water from 32° F to 212° F, or the average amount of heat per 1° F in this range. A **large caloric** is 1/100 of the heat required to raise the temperature of a kilogram of water from 0° C to 100° C or the average amount of heat per 1° C. The large caloric is equal to 1000 small calories and to 3.9683 Btu. The heat given up or absorbed by a body between two temperatures, providing no change of state or of allotropic form is involved, is known as **sensible heat**. The heat given up or absorbed by a body when a change of state takes place and no change of temperature is involved is known as **latent heat**. For example, a pound of water absorbs 180 Btu of sensible heat when being heated from 32° to 212° F, and absorbs 970.4 Btu of latent heat when one pound of water at 212° F is changed to steam at 212° F. Sensible heat and latent heat are used frequently in combustion calculations, particularly in problems dealing with flue-gas losses. Their significance is indicated in describing gross and net heating value of fuels.

The **gross heating value** of a fuel is the total heat developed by the combustion of a fuel at constant pressure after the products of combustion are cooled back to the

starting point, assuming that all of the water vapor produced is condensed; that is, the gross heating value includes both sensible and latent heat. The **net heating value** of a fuel is defined as the heat developed by the combustion of a fuel at constant pressure after the products of combustion are cooled back to the starting point, assuming that all of the water vapor remains uncondensed. Accordingly, the net heating value includes only sensible heat. The starting point usually is taken at either 32° F or 60° F. A starting point of 60° F has been used in all the tables and figures in this chapter, as it is generally the base for combustion calculations in the steel industry.

When a fuel contains neither hydrogen nor hydrocarbons, no water vapor is produced by combustion and the gross and net heating value will be the same, as in the case of burning carbon or carbon monoxide. The heating value or calorific value of a fuel may be determined on a dry or wet basis. The determination may be made by laboratory tests employing **calorimeters**, or by calculation. The process of determining the calorific value of solid and liquid fuels by a calorimeter consists in completely oxidizing the fuel in a space enclosed by a metal jacket (called the **bomb**) so immersed that the heat evolved is absorbed by a weighed portion of water contained in an insulated vessel. From the rise in temperature of the water, the heat liberated by one gram of the fuel is calculated. The best types of calorimeters for solid and liquid fuels are those called **oxygen-bomb calorimeters** in which the fuel is burned in the presence of compressed oxygen. Gas calorimeters are of different construction to permit volumetric measurement of the gas and its complete combustion under non-explosive conditions, as well as absorption of the heat produced in a water jacket. The **Junkers-type continuous-flow calorimeter** is a common type. The usual basis for reporting the calorific value of a gas is **gross Btu per cubic foot of saturated gas measured at 60° F and 30 in. Hg**. A **saturated gas** is one which contains the maximum amount of water vapor it can hold without any condensation of water taking place.

The heating value of a given fuel can be obtained by multiplying the calorific value of each gas by its per-

^(a)From "Fuel-Flue Gases"—American Gas Association—420 Lexington Ave., New York.

*For gases saturated with water at 60° F, 1.73% of the Btu value must be deducted.

centage of the total fuel volume, and then totaling the individual Btu values of the separate constituents. The heat of combustion for various dry elementary gases may be found in Table 3—II. For instance, the gross heating value of dry blast-furnace gas is 92.58 Btu per cu. ft. for the composition given below, calculated as follows:

Composition of Gas	Composition by Volume (%)	Gross Heating Value Btu per cu. ft. each Component	Gross Heating Value of each Fraction
CO ₂	12.76	0.0	0.0
CO	25.69	321.8	82.67
H ₂	3.05	325.0	9.91
N ₂	58.50	0.0	0.0
Total.....	92.58

In the calculation of the heating value of gases saturated with water vapor, the volume of water vapor must be deducted from the unit volume of gas. For instance, a cubic foot of dry CO gas has a heating value of 321.8 Btu, but when saturated with water vapor at 60° F and 30 in. Hg, a cubic foot has a heating value of only 316.2 Btu. The amount of water vapor present in saturated mixtures can be calculated from data in Table 3—III, as discussed later under "Gas Laws."

Thermal Capacity, Heat Capacity and Specific Heat—The thermal capacity or heat capacity of a substance is expressed as the amount of heat required to raise the temperature of a unit weight of the substance one degree. The British system uses Btu per lb. per ° F, while the metric system uses cal. per gm. per ° C. The specific heat of a substance is the ratio of the heat capacity of that substance to the heat capacity of water. Thus, specific heat is always a ratio, expressed as a number; for example, the specific heat of wrought iron is 0.115. There is no further designation, as this means that if it takes a certain number of Btu to heat a certain number of pounds of water a certain number of degrees F, it will take only 0.115 times as many Btu to heat the same number of pounds of wrought iron the same number of degrees F, and the same figure, 0.115, obviously applies if the metric system has been used. The amount of heat required to raise the temperature of equal masses of different substances to the same temperature level varies greatly; that is to say, the specific heat varies greatly; also the specific heat of the same substance varies at different temperatures. Usually, it is necessary to know the amount of heat required to raise the temperature of a substance some appreciable amount. For that purpose, formulae and tables are usually accessible in handbooks for supplying the mean specific heat between various temperature levels. Two values of specific heat for gases are usually given: (1) specific heat at constant pressure, and (2) specific heat at constant volume. The difference is due to the heat equivalent of the work of expansion caused by an increase of volume resulting from a temperature rise. Normal combustion practice with gases in steel plants deals with a constant pressure condition (or nearly so), and for this reason specific heat at constant pressure is used. The mean specific heat is the average value of the specific heat between two temperature levels. It is obtained by integrating the equations for instantaneous specific heat over the temperature limits desired, and dividing this quantity by the difference between the temperature limits.

The heat content is the heat contained at a specified temperature above some fixed temperature. It is calculated by multiplying the weight of a substance by the mean specific heat times the temperature difference, or $H = \text{weight} \times \text{mean specific heat} \times (T_2 - T_1)$. For convenience in calculations with gases, the unit weight of the volume of a cubic foot of gas is often used.

Gas Laws—The volume of a gas varies in direct proportion to its absolute temperature and inversely as its absolute pressure (Charles' Law). Absolute temperature is the temperature above minus 459.6° F at 29.921 inches of mercury column in the English system, and the temperature above minus 273° C at 760 mm. of mercury in the metric system. In combustion calculations using the English system, 460° F and 30 in. Hg are assumed sufficiently accurate for all practical purposes. For instance, the volume of 40,000 cu. ft. of gas measured at 60° F and 30 in. Hg, when heated to 1800° F and 30 in. Hg, is equal to:

$$40,000 \times \frac{460 + 1800}{460 + 60} = 174,000 \text{ cu. ft.}$$

and the volume of 40,000 cu. ft. of fuel gas measured at 60° F and 8 in. Hg gage pressure is equal to 31,579 cu. ft. at standard conditions (60° F and 30 in. Hg), calculated as follows:

$$40,000 \times \frac{30}{30 + 8} = 31,579 \text{ cu. ft.}$$

The total pressure of any gas mixture is equal to the sum of the pressures of each component. Each component produces a partial pressure proportional to its concentration in the mixture. Therefore, in a mixture of water vapor and any other gas, each exerts a pressure proportional to its percentage by volume, and since water has a definite vapor pressure at various temperatures, as shown in Table 3—III, the concentration of water vapor in a gas is limited. When this limit of water vapor is reached, the gas is said to be **saturated**. Any drop in temperature or increase in pressure from that point will cause condensation of the water vapor; for instance, the water vapor in 1000 cu. ft. of saturated fuel gas measured at 60° F and 30 in. Hg is calculated as follows:

$$1000 \times \frac{0.522}{30} = 17.40 \text{ cu. ft.}$$

(0.522 is the partial pressure of water vapor in a saturated mixture at 60° F and 30 in. Hg—see Table 3—III). The amount of water vapor which will condense at various temperatures may be ascertained by the use of Table 3—III.

In many combustion calculations it is necessary to convert volumes to weights and vice versa. Such conversions may be made very conveniently by using the molar units, pound-mol. (abbreviated lb.-mol.) or gram-mol. (abbreviated gm.-mol.) A lb.-mol. (or gm.-mol.) is that quantity whose weight in pounds (or grams) is the same number as the number of the molecular weight. Thus, the molecular weight of oxygen is 32, so that a lb.-mol. of oxygen is 32 lbs. of oxygen (or a gm.-mol. of oxygen is 32 gm. of oxygen). In the English system, a lb.-mol. of any gas theoretically occupies 359 cu. ft. at 32° F and 29.92 in. Hg; or at 60° F and 30 in. Hg, the usual reference points for combustion problems in the steel industry, a lb.-mol. occupies 378.4 cu. ft. (**Avogadro's Principle**). Actually some gases deviate slightly from this figure, but for gases and air at pressures normally encountered in combustion practices, the ideal figure is entirely satisfactory. The simplicity of using the lb.-mol. for weight or volume conversions is shown by the following example. The weight of a cubic foot of dry air is:

$$0.21 \text{ (\% vol. of } O_2 \text{ in air)} \times \frac{32 \text{ (molecular wt. of oxygen)}}{378.4} = 6.72$$

$$0.79 \text{ (\% vol. of } N_2 \text{ in air)} \times \frac{28 \text{ (molecular wt. of nitrogen)}}{378.4} = 22.12$$

$$\text{Weight in lbs. of a lb.-mol. of air} = 28.84$$

$$\frac{28.84}{378.4} = 0.076 \text{ lbs. (wt. per cu. ft. of dry air at 60° F and 30 in. Hg)}$$

The volume of a pound of dry air at 60° F and 30 in. Hg is:

$$\frac{378.4}{28.84} = 13.1 \text{ cu. ft.}$$

The relation of an ideal gas to its volume and pressure is expressed by the formula:

$$PV = NRT$$

where:

- R = gas constant
- P = absolute pressure
- V = volume
- N = number of mols.
- T = absolute temperature of gas

The numerical value of R in the above equation depends upon what units (English or metric) are used to measure P, V, N and T. Values of R for various combinations of units for measuring the other quantities are as follows:

T	P	V	N	R
° F abs.	lb. per sq. in.	cu. ft.	lb.-mol.	10.72
° F abs.	inches of Hg	cu. ft.	lb.-mol.	21.85
° C abs.	mm. of Hg	liters	gram-mol.	62.37
° C abs.	atmospheres	liters	gram-mol.	0.08205

The application of the foregoing formula is shown by the following example. Calculate the volume occupied by 100 lbs. of natural gas having a composition of 80 per cent CH_4 , 18 per cent C_2H_6 , and 2 per cent N_2 by volume at a gage pressure of 8 in. Hg and a temperature of 100° F.

$$P = 30 + 8 = 38 \text{ in. Hg absolute}$$

The weight in lbs. of a lb.-mol. of the gas is:

$$\begin{aligned} CH_4 &= 0.80 \times 16 = 12.8 \\ C_2H_6 &= 0.18 \times 30 = 5.4 \\ N_2 &= 0.02 \times 28 = 0.56 \\ &\hline &18.76 \end{aligned}$$

$$N = \frac{100}{18.76} = 5.33$$

$$T = 100 + 460 = 560$$

Substituting these values in the equation for a perfect gas ($PV = NRT$):

$$\begin{aligned} 38 V &= 5.33 \times 21.85 \times 560 \\ V &= 1716 \text{ cu. ft.} \end{aligned}$$

Combustion Calculations—The combustion of fuels is carried out by chemical reaction with air, and occasionally with air enriched with oxygen, or with pure oxygen. **Dry air** is a mixture of the following gas volumes under average conditions:

N_2	= 78.03%
O_2	= 20.99%
Argon	= 0.94%
CO_2	= 0.03%
H_2	= 0.01%
Total	= 100.00%

In combustion calculations it is customary to include all elements in dry air (other than oxygen) with the nitrogen, as shown below:

	% by Volume	% by Weight
Oxygen	20.99	23.11
Nitrogen	79.01	76.89

Only the oxygen in the air reacts with a fuel in combustion processes. The nitrogen acts as a diluent which must be heated up by the heat of the reaction between the oxygen and the fuel. It, therefore, reduces the temperature of the flame and reduces the velocity of combustion.

Water vapor which is present in air also acts as a diluent. The amount of moisture present in air is generally stated in terms of humidity. Air is capable of being saturated with water vapor the same as other gases as described under "Gas Laws." Air which is saturated completely with water vapor has a humidity of 100 per

cent; if only 50 per cent saturated, it has a humidity of 50 per cent (Table 3—IV).

The principal combustion reactions are:

The amount of oxygen required and consequently air, together with the amount of the resultant products of combustion, may be calculated by the use of molecular weights and the proper chemical equation. For instance, it will require $(32 \div 12)$ or 2.667 lbs. of O_2 to burn 1 lb. of C, and since dry air contains 23.11 per cent by weight of O_2 , the weight of dry air required to burn one pound of carbon will be $(2.667 \div 0.2311)$ or 11.540 lbs. The product of combustion, CO_2 , will amount to $[(12 \div 32) \div 12] = 3.667$ lbs.

Combustion calculations using gases are more conveniently made in volumetric units. For instance, to burn a cubic foot of CO completely to CO_2 requires $\frac{1}{2}$ cu. ft. of O_2 in accordance with the molecular relationship in the equation. The dry air required would be $(0.5 \div 0.209)$ or 2.382 cu. ft. For burning a cubic foot of methane, CH_4 , to CO_2 and H_2O , the air required would be $(2.0 \div 0.209)$ or 9.528 cu. ft.

Combustion calculations are necessary to determine the air requirements and the products of combustion for burning fuels of various compositions. The per cent of air

used above theoretical requirements is called per cent excess air; the per cent below, the per cent deficiency of air. Typical combustion data on a dry basis for burning gaseous fuels of the compositions stated are shown in Table 3—V. In making calculations to include the water vapor which may be present in a saturated or partially saturated gas and in air, the same general method may be used by adding water vapor to the fuel-gas composition, and by adding the volume of water vapor which is introduced through air in the products of combustion column, headed H_2O .

In order to maintain combustion, a fuel must, after it has been ignited, be able to impart sufficient heat to its air-gas mixture so that it will not drop below ignition temperature, the minimum point of self-ignition. Too lean or too rich a mixture of a fuel with air is unable to support combustion. An upper and lower limit of flammability exists for all gases. The limits of flammability, as well as ignition temperatures, for a number of gases are shown in Table 3—VI.

In the design of burners or in the selection of fuel for a specific purpose, consideration of velocity of combustion is of major importance. Since gaseous fuels are composed usually of a mixture of combustible gases, a knowledge of the relative combustion speed of each elementary gas will provide means for evaluating this factor in any gaseous mixture. The velocity of combustion, or rate of flame propagation, of a given fuel, is influenced by three factors: (1) degree to which the air and gas are mixed, (2) temperature of the air-gas mixture, and (3) contact of the air-gas mixture with a hot surface (catalyst). By intimately mixing air and gas, combustion may be accelerated and a shorter, sharper flame developed. In the case of a gas containing large amounts of hydrogen, intimate mixing will provide a combustion reaction of explosive velocity relative to that of a gas containing large amounts of methane. Inert

**Maximum reported in Bulletin 279, Bureau of Mines.

gases, such as carbon dioxide and nitrogen, present in fuel gases or in a gas-air mixture, reduce combustion velocity. The proportion of nitrogen in a fuel gas-air mixture may be reduced by oxygen enrichment of air for combustion, and combustion speed may, by this means, be accelerated many fold. Such measures also will raise the flame temperature. The use of preheated air for combustion also accelerates combustion of gases. In order to burn large volumes of fuel in a small space, a mixture of air and gas is sometimes directed against a hot, incandescent surface. By increasing the velocity of combustion, higher temperatures are localized close to the burner point. This condition is desirable for some processes and highly undesirable for others. For instance, the scarfing process requires a highly intensive localized heat, while the heating of steel for rolling requires a soft, even distribution of heat over the full surface of the pieces being heated. In order to reduce combustion speed of a gaseous fuel, the air and gas streams may be stratified to produce slow mixing. Such a method creates a **diffusion flame**, a long flame of relatively uniform temperature.

Theoretical flame temperature is the temperature which would be attained by the products of combustion if the combustion of a fuel took place instantaneously, and there were no loss of heat to the surroundings. Such a condition never exists, but theoretical flame temperature represents another measure for comparing fuels. Fuels which develop a high flame temperature by combustion are more capable of producing a higher thermal efficiency in practice than those which develop low flame temperatures. The efficiency of heat utilization is the relation of the total heat absorbed by a substance to the heat supplied. Since the temperature level at which waste gases leave a furnace is usually fixed within a relatively narrow range, the higher the flame temperature the higher the potentiality for heat absorption by the substance to be heated. The theoretical flame temperature of a fuel may be calculated by balancing the sum of the net heating value of a given quantity of fuel and the sensible heat of the air-gas mixture against the heat content of the products of combustion. Theoretical

flame temperature so calculated should be corrected for dissociation of CO₂ and H₂O at temperatures in excess of 3000° F. The theoretical flame temperatures for a number of important gaseous fuels are given in Table 3—XVI. The reader is referred to "Combustion" published by the American Gas Association for a full explanation of the calculation of theoretical flame temperatures and the dissociation of gases at elevated temperatures.

There are a number of factors which determine the character, size and shape of a gas flame. Gases burned at very high combustion velocity will produce very little or no luminosity regardless of the kind of gas. The velocity and volume with which the air-gas stream leaves a burner or furnace port, the fuel-air ratio, and the amount of non-combustible material in the fuel will influence the length and shape of a flame. The kind of gas to be burned has a very great effect upon the character of the flame. Carbon monoxide and hydrogen burn with an invisible to a clear blue flame, while the hydrocarbon gases, methane, ethane, etc., are capable of developing highly luminous flames. The principal reason that these gases burn with a luminous flame is due to the thermal breakdown of the hydrocarbons into carbon and hydrogen, and under combustion conditions which permit this, the carbon particles are heated to incandescence thereby giving the flame its luminous appearance. The luminosity of a flame may be decreased or increased by varying the supply of air. A deficiency of air below theoretical requirements will increase luminosity and it also usually will lengthen the flame. An excess of air will decrease luminosity and shorten the flame with most burners or furnace ports. Increasing the temperature of preheat of the air for combustion will reduce luminosity, as is also the case when water vapor (steam), which may be introduced with the gas, air, or for atomization of liquid fuels, is increased. A luminous flame has a number of desirable qualities, the principal one being its greater ability to transfer heat by radiation from a fixed temperature level. However, it should be noted that a luminous flame is obtained usually at a lower temperature level than when the same fuel is burned with a lower degree of luminosity.

SECTION 4

HEAT FLOW

Heat flow is caused by a difference in temperature, and heat is transmitted in three ways, namely, by conduction, by convection, and by radiation.

Conduction is the transmission of heat through a solid body without visible motion of the body, as through a steel bar. The amount of heat transferred through a homogeneous solid by conduction is expressed by the formula:

$$Q = \frac{K A \Delta t}{L}$$

where Q = Btu transmitted per hour

K = conductivity, in Btu per hour per sq. ft. per °F per inch of thickness

A = area in sq. ft.

Δt = temperature difference in °F

L = length of heat transfer path in inches.

The flow of heat through a non-homogeneous solid body by conduction is expressed by the formula:

$$Q = \frac{\Delta t}{\frac{L_1}{K_1 A_1} + \frac{L_2}{K_2 A_2} + \frac{L_n}{K_n A_n}}$$

where:

L_1, L_2 and L_n = the respective length of heat transfer path through the various resistances.

K_1, K_2 and K_n = the corresponding conductivity factors of the various resistances expressed in Btu per hr. per sq. ft. per °F per inch of thickness.

A_1, A_2 and A_n = the corresponding areas expressed in square feet.

Convection—When heat is transmitted by the mechanical motion of gas or water currents in contact with a solid, or by gas currents in contact with a liquid, the transfer of heat is by convection. In the transfer of heat by convection, it is necessary to conduct heat through the relatively stationary film between the moving and stationary bodies. This film becomes thinner as the velocity of the currents parallel to its surface increases. The transfer of heat by convection is expressed by the formula:

$$Q = a_s A \Delta t$$

where:

Q = Btu transmitted per hour

a_s = film coefficient (Btu per sq. ft. per °F per hr.) dependent upon the velocity, specific gravity and viscosity of the moving fluid, and the conductivity of the film.

A = area in sq. ft.

Δt = temperature difference

Radiation refers to the transmission of heat through space without the help or intervention of matter. This is the means by which the heat of the sun reaches the

earth, and by which much of the heat of combustion of fuels is utilized in high-temperature processes in the steel industry. When radiant energy strikes any body a certain proportion of the total is reflected, while that absorbed is reconverted to heat energy. A perfectly black body is one that will not reflect radiations falling upon it but absorbs them all. The coefficient of reflectivity of a body receiving radiation is equal to one minus its black body coefficient. Emissivity refers to the rate at which a body radiates heat, and this rate depends upon the temperature of the body and the nature of its surface. Kirchhoff's Law shows that the absorptivity and emissivity of a given surface are numerically equal at the same temperature. The Stefan-Boltzmann Law states that the total energy of a black body is proportional to the fourth power of its absolute temperature. The net effect of heat transfer between two bodies is shown by the equation:

$$Q = 0.174 EA \left[\left(\frac{T_1}{100} \right)^4 - \left(\frac{T_2}{100} \right)^4 \right]$$

where:

Q = Btu transmitted per hour

0.174 = radiation factor for a perfect black body

E = emissivity or "black body" factor

A = sq. ft. of surface

T_1 = temperature of body giving off heat, in °F absolute

T_2 = temperature of body receiving heat, in °F absolute

The emissivity factors for various materials at specified temperatures are shown in Table 3—VII.

Table 3—VII. Emissivity Factors (A perfect absorber or radiator = 1)

Material	E
Polished aluminum at 445°F	0.039
Polished aluminum at 1075°F	0.056
Polished brass at 570°F	0.031
Polished nickel at 715°F	0.086
Polished nickel plated steel at 72°F	0.052
Bright tinned steel plate at 75°F	0.071
Polished mild steel	0.288
Cast iron—machined—at 72°F	0.437
Cast iron—liquid—at 2425°F	0.282
Cast iron—rough oxidized	0.97
Mild steel—dull oxidized—from 79° to 672°F ..	0.96
Firebrick glazed through use at 1830°F	0.75
Silica brick (rough)	0.81

In the generation of heat from fuels, the character of the flame and its proximity to the receptor of heat is particularly significant in the transfer of heat by radiation. The amount of heat transferred from a flame varies widely and in proportion to its degree of luminosity. The transfer of heat by radiation varies inversely with the square of the distance between the transmitter and receptor of radiant energy. For that reason, flames should be kept close to the substance to be heated where high heat transfer rates are desirable.

SECTION 5

SOLID FUELS AND THEIR UTILIZATION

The solid fuels have played a significant role in the evolution of our modern, industrial civilization. Coal in particular has been of far-reaching importance in that it has provided the prodigious amount of energy essential to the development of the iron and steel industries. Vast quantities of this energy source remain to be exploited but the rate of utilization far exceeds the rate at which coal is being formed. It follows that the efficient use of the remaining supply is desirable. Toward this end, modern coal research is directed.

The earliest-formed coals thus far encountered occur in the Silurian strata of Bohemia. It is not until Lower Carboniferous time (see Table 3—VIII), however, that the source materials of coal began to accumulate in significant quantities. Every continent, including Ant-

arctica, contains some coal and no system of rocks younger than the Silurian is devoid of this important substance. In North America major concentrations of source materials were accumulated during the Carboniferous, Cretaceous and Tertiary periods. A similar statement can be made for Europe but, in contrast, some of the most important Asiatic coals occur in Triassic and Jurassic rocks.

Coal Resources—The known coal deposits in the United States are greater than those of any other country. Based on U. S. Geological Survey estimates, the reserves of all grades of coal were in excess of 2,500 billion net tons in 1950. This would be enough to supply requirements for a long period in the future if all present coal reserves were available economically and of ac-

ceptable quality. A considerable quantity of the reserves of better quality coking coal have been utilized in the past and it is apparent that in the future it will be necessary to use coals requiring efficient extraction, cleaning, and other processing to assure proper utilization.

For obvious reasons, the steel industry has been striving to use coals which would produce metallurgical coke of optimum quality with a minimum of processing. Concentrations of coals of this class are found chiefly in the Appalachian area, although isolated deposits also exist in some Central and Western states. The preponderance of total coal reserve in the United States is in the form of lower-rank coals in the Great Plains, the Rocky Mountains, the Pacific Coast states and the Gulf region (see Figure 3-1). The manner in which this material can be used most effectively remains to be determined.

Origin and Composition of Coal—Coal is known to be a complex mixture of plant substances which have been altered in varying degrees by physical and chemical processes. Ordinarily, plant material, upon death, fails to accumulate because micro-organisms induce complete decomposition. Under certain circumstances, notably those associated with forested fresh-water swamps, the activities of bacteria and fungi are inhibited by antibiotic solutions which are common in this type of environment. As a result the rate of accumulation exceeds that of decomposition and dispersion. Under such conditions a brown fibrous deposit known as **peat** is formed. Peat is the first step in the formation of coal.

Peat deposits formed millions of years ago subsequently were submerged through vertical movements of the earth's crust, in which position they became covered by deposits of sedimentary rocks. Later movements of the earth's crust raised many of these deposits to various heights above sea level. In the meantime, the peat had been changed, through agencies of biological action, pressure, and heat, into coal. The better ranks of coal in this country were formed during the Carboniferous period, the geologic period when conditions were most favorable for plant accumulation and decomposition. Included in the present deposits that originated in that period are the coal fields of the Appalachian and Central states.

The rate at which peat forms depends upon the rapidity of plant growth and the manner in which tissue increment is related to the rate of decomposition. It has been

estimated that approximately one century is required to form a deposit of mature, compacted peat one foot in thickness. Certain studies of volatile matter relationships suggest that a three-foot-thick deposit of mature peat is required to produce a one-foot-thick layer of bituminous coal. These and other data indicate that a coal seam which is several feet thick may require a time span of thousands of years for its formation. If, in the course of time, the peat is subjected to the necessary conditions it becomes modified to **brown coal** and, when adequately consolidated, to **lignite**. From the lignitic stage, the material passes progressively through the sub-bituminous, bituminous, semi-anthracite and anthracite stages with a gradual change in the composition of the individual components of the complex mass. The elementary compositions of coal shown in Table 3-IX, illustrate the gradual concentration of carbon and loss of oxygen in the various stages of coal formation.

Peat varies in appearance from a light, brown-colored, fibrous material to a very black and dense, muck-like sediment. Lignite is usually brown in color and commonly shows a woody texture. It contains a large amount of moisture and usually disintegrates to a powdery mass as it dries on exposure to air. Sub-bituminous coal varies in color from very dark brown to black and fractures irregularly. Bituminous coal is black in color and usually exhibits a banded structure due to the alternate dull and vitreous layers of varying thickness. Coals of the high-volatile bituminous rank commonly burn with a smoky, yellow flame. Anthracite coal is black, hard and brittle and has a high luster. It ignites less easily than bituminous coal and burns with a short bluish-yellow flame producing little smoke. The characteristics of semi-anthracite coal are intermediate between those of bituminous coal and anthracite.

All of the solid natural fuels contain both combustible and non-combustible materials. The combustible material is composed mainly of carbon, hydrogen and, to a lesser extent, sulphur. The non-combustible constituents are water, nitrogen and oxygen, and a variety of mineral materials usually referred to as **ash**.

The bituminous coals are of greatest interest in view of the fact that essentially all coking coals fall in this category. The lustrous black bands which are conspicuous in a lump of bituminous coal are generally referred to as **vitrain** although some American coal petrographers

employ the term **anthraxylon** in preference. Following U. S. Bureau of Mines terminology, the anthraxylon is derived from woody plant tissues and is surrounded by a dull ground mass made up of translucent attritus, opaque attritus and fusain. The attrital portion is composed of finely comminuted fragments of altered plant materials. Fusain is a friable, charcoal-like substance derived from woody tissues and is a term used universally without modification.

In addition to the readily recognizable bands of vitrain and fusain, European and Asiatic coal investigators have found it useful to identify silky, minutely striated layers within a coal as **clarain**. Layers of dull, compact coal are called **durain**. Thus, coal seams can be thought of as being composed, usually, of various mixtures of **vitrain**, **fusain**, **clarain** and **durain**, each occurring in the form of layers which are visually observable. Coals made up largely of vitrain and clarain are spoken of as **bright coals** whereas coals containing a high percentage of durain are called **splint coals**. Bright coals are generally better coking coals than splint coals, vitrain apparently playing an important part in the carbonization process. Fusain will not coke, but in small percentages it may actually increase coke strength. If present in concentrations greater than 18 to 20 per cent it begins to exert a deleterious effect. The fixed carbon content is higher and the volatile matter content is lower in fusain than in the other "banded ingredients."

Microscopic study has shown the banded components to be composed of identifiable plant entities called **phyterals**, but of greater significance is the fact that the vitrain, fusain, clarain and durain are made up of numerous components or **macerals** which can be defined by their physical and chemical properties. Durain, for example, may include several macerals (vitrinite, semifusinite, micrinite, cutinite, etc.) which are easily distinguished by their differing optical properties. It is probable that additional information regarding the nature and variability of these individual coal components will contribute materially to the effective and efficient utilization of all types of coal.

Chemical Composition and Coal Classification—There are two methods commonly employed to determine the chemical composition of coal; namely **ultimate analysis** and **proximate analysis**. An ultimate analysis determines the quantities of carbon, hydrogen, oxygen, nitrogen, sulphur, chlorine and ash in dry coal; a proximate analysis determines the fixed carbon, volatile matter, moisture and ash contents and, usually, the sulphur content. The proximate analysis which also includes determina-

tion of sulphur is used most commonly, since it furnishes most of the data required for normal commercial evaluations.

In order to provide a measure of the distillation products obtainable from coal used in coal-chemical and hydrogenation plants, another method of analysis called the **tube distillation assay test** (also called **progressive distillation**) is used. Table 3—X compares the composition of a bituminous coal as derived by the three methods mentioned.

Using data provided by chemical, physical or petrographic analyses, coals are classified according to **grade**, **rank** and **type**. The grade is determined by the amount, nature and fusibility of the ash and by the sulphur content. Classification according to rank is based upon the degree of metamorphism within the coal series from the level of lignite to that of anthracite coal. The American Society for Testing Materials ranks coals according to their fixed-carbon content on a dry basis, and the lower rank coals according to Btu content on a moist basis. The classification of coals by rank adopted by the American Society for Testing Materials (A.S.T.M. Specification D388-38), is shown in Table 3—XI.

In the United States, coals are also classified into **types** and such terms as **bright**, **semi-splint**, **splint**, **cannel** and **boghead** coal are applied. The data required are obtained from microscopic studies. The United States Bureau of Mines standards indicate that bright coal must have less than 20 per cent opaque matter, semi-splint must have between 20 and 30 per cent, and splint coal must be made up of more than 30 per cent of this ingredient. Cannel and boghead coals are **non-banded** and are characterized by a small percentage of anthraxylon (vitrain). Boghead possesses a high percentage of volatile oils and gases, and contains an abundance of algal material. Cannel, or candle coal, is so named because it can be ignited with a match or a candle flame and it burns with unusual brilliance. Cannel coal is non-coking, often contains large quantities of spore and pollen materials, and like boghead, has a high content of volatile oil and gas.

Mining of Coal—Seams of coals vary in thickness throughout the world from a fraction of an inch to over 250 feet. In this country the thickest seams are found in the sub-bituminous coals of the West, one of which approaches 100 feet. In the East, the Mammoth bed in the anthracite fields of Pennsylvania attains a thickness of 50 to 60 feet but is found to be quite variable when traced laterally. The Pittsburgh seam at the base of the Monongahela series in the Appalachian area is note-

Table 3—X. Comparison of Results of Common Methods for Analyzing a High-Volatile Bituminous Coal

Proximate Analysis Dry Basis (%)		Progressive Distillation Dry Basis (%)		Ultimate Analysis Dry Basis (%)	
Ash	7.16	Coke ^{aw}	70.36	Ash	7.16
Fixed Carbon (by diff.)	59.98	Tar	5.02	C	79.41

Table 3—XI. Classification of Coals by Rank^a

Legend: F.C.—Fixed Carbon.

V.M.—Volatile Matter.

Btu.—British thermal units

Class	Group	Limits of Fixed Carbon or Btu. Mineral-Matter-Free Basis ^a	Requisite Physical Properties
I. Anthracitic	1. Meta-anthracite	Dry F.C., 98 per cent or more (Dry V.M., 2 per cent or less)	Nonagglomerating ^b
	2. Anthracite	Dry F.C., 92 per cent or more and less than 98 per cent (Dry V.M., 8 per cent or less and more than 2 per cent)	
	3. Semianthracite	Dry F.C., 86 per cent or more and less than 92 per cent (Dry V.M., 14 per cent or less and more than 8 per cent)	
II. Bituminous ^d	1. Low volatile bituminous coal	Dry F.C., 78 per cent or more and less than 86 per cent (Dry V.M., 22 per cent or less and more than 14 per cent)	Either agglomerating or nonweathering ^f
	2. Medium volatile bituminous coal...	Dry F.C., 69 per cent or more and less than 78 per cent (Dry V.M., 31 per cent or less and more than 22 per cent)	
	3. High volatile A bituminous coal....	Dry F.C., less than 69 per cent (Dry V.M., more than 31 per cent); and moist ^e Btu., 14,000 ^g or more	
	4. High volatile B bituminous coal...	Moist ^e Btu., 13,000 or more and less than 14,000 ^g	
	5. High volatile C bituminous coal....	Moist Btu., 11,000 or more and less than 13,000 ^g	
III. Subbituminous	1. Subbituminous A coal.....	Moist Btu., 11,000 or more and less than 13,000 ^g	Both weathering and non-agglomerating
	2. Subbituminous B coal.....	Moist Btu., 9500 or more and less than 11,000 ^g	
	3. Subbituminous C coal.....	Moist Btu., 8300 or more and less than 9500 ^g	
IV. Lignite	1. Lignite	Moist Btu., less than 8300	Consolidated Unconsolidated
	2. Brown coal	Moist Btu., less than 8300	

^(a)This classification does not include a few coals which have unusual physical and chemical properties and which come within the limits of fixed carbon or Btu. of the high-volatile bituminous and subbituminous ranks. All of these coals either contain less than 48 per cent dry, mineral-matter-free fixed carbon or have more than 15,500 moist, mineral-matter-free Btu.

^(b)If agglomerating, classify in low-volatile group of the bituminous class.

^(c)Moist Btu. refers to coal containing its natural bed moisture but not including visible water on the surface of the coal.

^(d)It is recognized that there may be noncaking varieties in each group of the bituminous class.

^(e)Coals having 69 per cent or more fixed carbon on the dry, mineral-matter-free basis shall be classified according to fixed carbon, regardless of Btu.

^(f)There are three varieties of coal in the high-volatile C bituminous coal group, namely, Variety 1, agglomerating and nonweathering; Variety 2, agglomerating and weathering; Variety 3, nonagglomerating and nonweathering.

Computation of Mineral-Matter-Free Analyses

^(g)Mineral matter was taken as 1.1 times the ash. The values for fixed carbon and Btu. as given in the charts were calculated as follows:

$$\text{Moist fixed carbon} \times \frac{100}{100 - (\text{moisture} + 1.1 \text{ Ash})} = \text{dry, mineral-matter-free fixed carbon}$$

$$\text{Moist Btu.} \times \frac{100}{100 - 1.1 \text{ Ash}} = \text{moist, mineral-matter-free Btu.}$$

Moist, as used in the formulas, refers to the coal containing its natural bed moisture but not including visible moisture on the surface of the coal. For more accurate formulas that apply corrections for the sulphur in the coal, reference should be made to those for fixed carbon and Btu. as given in A.S.T.M. Standards on Coal and Coke.

worthy because of its exceptionally uniform thickness (approximately 7 feet) over thousands of square miles. Figure 3-2 shows the western portion of Pennsylvania in such a manner as to make clear the areal extent as well as the sub-surface relations of the coal-bearing formations of this region. Data are provided as to thickness of seams and distance between coals.

Coal seams may dip gently as shown in Figure 3-2, or they may be horizontal, or they may exist almost vertical with respect to the Earth's surface. Mining problems are often complicated by the fact that seams seldom remain in the same plane throughout their extent. Under present conditions, a coal bed must be at least 30 inches to 36 inches thick to be profitable for mining. Figure 3-2 shows, also, that coal seams vary in their distance from the Earth's surface. U. S. Geological Survey estimates of coal reserves do not include coal seams deeper than 3,000 feet from the surface, although in Great Britain and Europe coal seams at greater depth at present are being mined economically.

The mining of coal is performed by either one of two methods: (1) **Open work or stripping**, also called **contour mining**, or (2) **underground or closed work**. The first method involves removing the formation (overburden) above the seam by stripping with scrapers, bulldozers, or mechanically operated shovels, followed by removing the exposed coal. Stripping is applied to coal seams which are relatively close to the surface, particularly to thick seams underlying overburden not over 75 feet deep, although the development of larger equipment and improved techniques in recent years has justified removal of thicker layers of overburden than this. Production by strip mining has increased greatly since World War I due to reduced labor and material costs and a quicker return on capital investment compared to underground mining. In the United States, strip-mining accounted for nearly 24 per cent of the coal produced in 1950 and 22 per cent in 1951.

Underground mining is performed by either the **room-and-pillar** or the **longwall** method. The room-and-pillar method is in more common use in the United States, accounting for approximately 90 per cent of present underground mining. The longwall method is particularly adaptable to mining seams up to about $4\frac{1}{4}$ feet thick under conditions where the roof may be permitted to settle. It is used more extensively in the mines of the Middle West than in the East. There are a number of modifications applicable to each method. The room-and-pillar system consists essentially of working out rooms, chambers, or breasts in the coal seam from passages (entries) driven from the mine entrance. Entrance to an underground mine is by drift, shaft or slope. The rooms vary in width from about 12 feet to 40 feet, and from 150 feet to 300 feet in length, depending on such factors as weight and character of the overlying and underlying structure and thickness of seam. Pillars separating the rooms vary in width from 6 feet to 100 feet, depending on conditions and mining practice. These pillars are sometimes removed by retreat mining and the coal recovered.

In the longwall method, a continuous mining face is maintained in the coal seam. After mining, the roof is permitted to settle, thirty or forty feet from the mine working face. Waste rock is used to support the roof for maintenance of haulage roadways, which include main roads running diagonally like the spokes of a wheel from a central shaft and auxiliary roads running through the intervening areas.

Prior to the advent of mechanical mining, undercutting of the coal seam preparatory to blasting was done manually. Production per man was low by this method

and required a number of working faces in the mine to produce high mine tonnage. Hand loading of coal into mule-drawn cars was the prevailing practice for many years until development of machinery for both cutting and loading. Electric trolley-type locomotives capable of hauling longer underground trains of cars of increased capacity displaced mule-drawn trains as mine capacity increased.

In a modern underground mine the coal is emptied from the mine car by a rotary dumper which may have a capacity of as many as 37 cars. From the dumper the coal is fed by way of a conveyor or elevator to a shipping station or cleaning plant.

Continuous Mining—The cutting machines and loading machines characteristic of mechanical mining are both single-purpose units, and each performs essentially a single function of mining at the working face. After either unit has completed its work it must be withdrawn from the face to allow other units of the production set-up to move up to the face to carry out succeeding functions. To keep all operating units working at full efficiency, it is necessary to have additional working places near at hand so that the single-purpose machines can enter the places in rotation and carry out their respective functions without interference.

To eliminate some of the difficulties attendant upon the addition of extra working places, multi-purpose machines known as **continuous miners** have been developed and the operation carried out by such machines has been given the name **continuous mining**. Continuous miners combine in a single unit the actions of dislodging the coal from the solid seam and loading it into some unit of a transportation system. Such machines, therefore, combine in one operation the separate steps of cutting, drilling, blasting and loading common to modern mechanical mining methods.

There are several types of continuous miners in operation, one of which is the Konnerth mining machine. This machine is unique in that it employs electrically operated hammers to vibrate the coal at the working face so powerfully that it is shattered and falls to the floor to be picked up by the machine and loaded directly by conveyor into a shuttle car. The machine has two toothed-chain cutters which simultaneously make two horizontal cuts in the coal close to the floor. Two other cutters make vertical cuts in the coal to block out a section to be broken and loaded. After the section has been blocked out by the cutters, the two vibrating hammers of the machine, delivering 1800 blows per minute, are brought into contact with the face of the coal to break it. The cutter bits of the horizontal chain cutters pick up the shattered coal and move it continuously onto the conveyor of the machine.

In certain types of coal, light charges of explosives may be used to partially break the blocked-out coal before the hammers of this type of machine are brought into operation.

Continuous miners of some other types employ toothed-chain cutters to rip the coal from the face, or auger-type cutters that bore into the face, the cut coal in both cases being carried by a conveyor on the machine to a shuttle car or other means of transportation.

Coal Preparation—Specifically, the objective of coal cleaning (often called washing) is removal of solid foreign matter, such as rock and slate, from the coal prior to its use. Reduction of ash and sulphur contents; control of ash fusibility; increase of heating (calorific) value; and improvement of coking properties of the coal can be achieved by this practice. From a coal-cleaning standpoint, the impurities in coal are of two types; namely, those which cannot be separated from the coal,

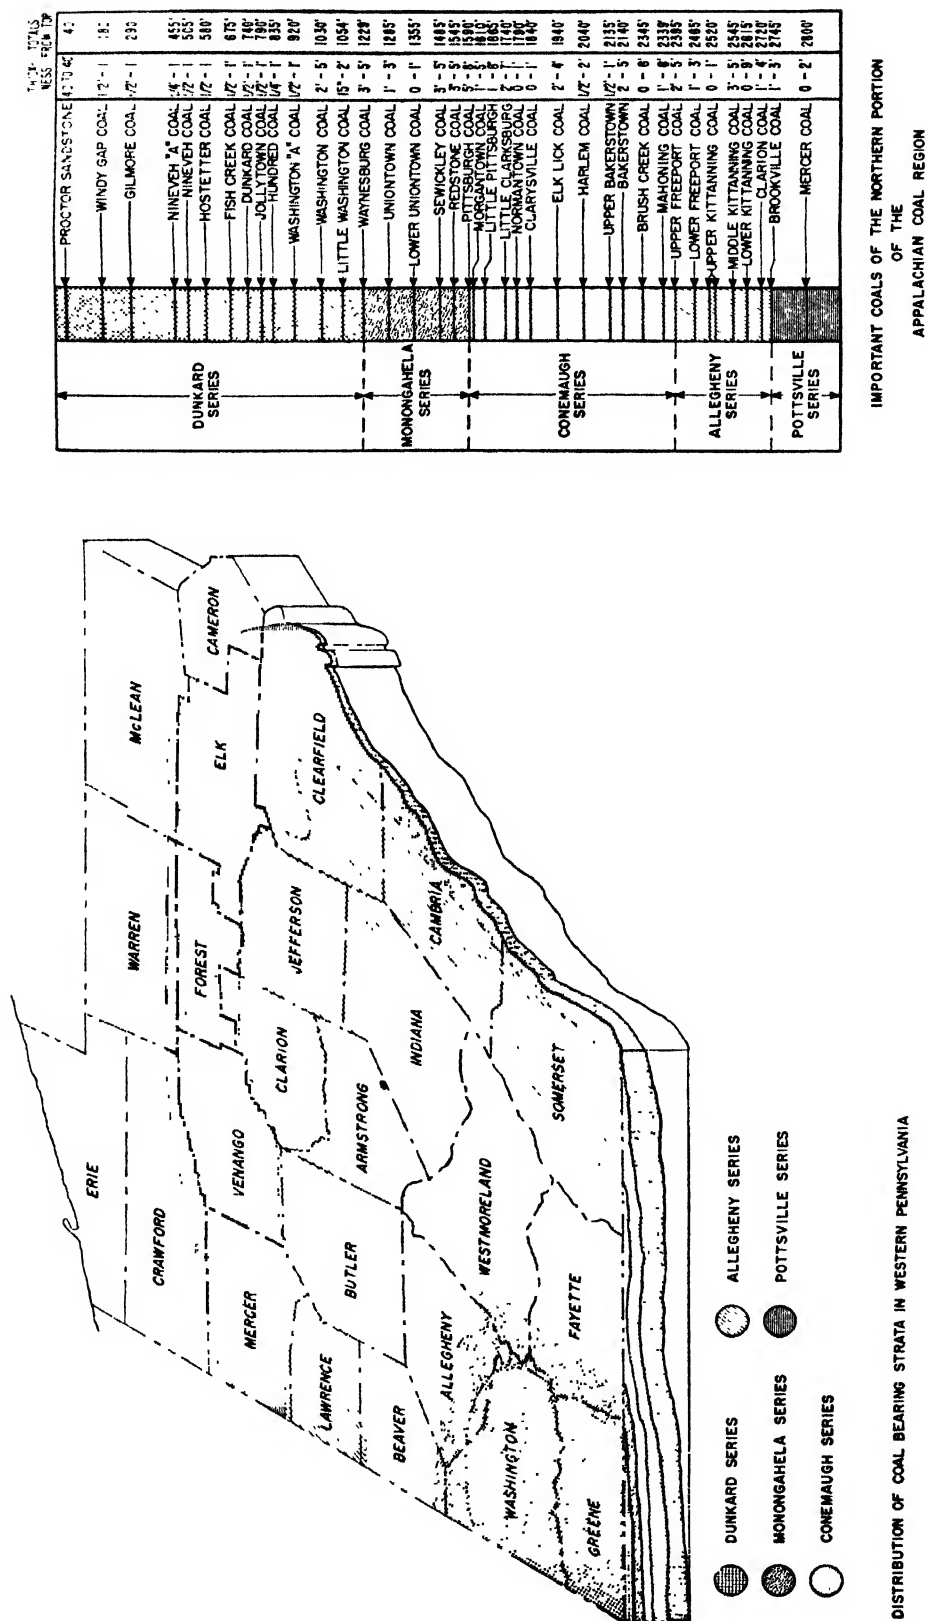

Fig. 3-2. (Left) Distribution of coal-bearing strata in Western Pennsylvania. (Right) Important coals of the northern portion of the Appalachian coal region.

usually called **fixed impurities**; and those which can be removed, herein referred to as **free impurities** or **refuse**. Altogether, these impurities are of eight types, named as follows: (1) residual inorganic matter of the coal-forming plants from which the coal was derived; (2) mineral matter washed or blown into the coal-forming mass during the periods of its formation; (3) pyrites (FeS_2) formed by the reaction of iron sulphate with coal-forming matter; (4) sedimentary deposits during the coal-forming periods which appear as partings, sometimes called "bone," that usually must be mined with the coal; (5) massive deposits formed through deposition on bedding planes; (6) saline deposits, somewhat rare in coal beds of the United States; (7) slate, shale, clay, etc. from the underlying and overlying strata accidentally included in mining; and (8) water or moisture, which includes that naturally carried by the coal in air-dry condition, and excess moisture producing a condition of wetness. Items (1), (2) and, for the most part, (3) form **fixed ash**, while (4), (5), (6), and (7) are partly **free ash-forming materials** that can be removed by hand-picking and suitable mechanical cleaning treatments. Item (8) involves drying operations differing from those required to separate mineral impurities, which is the primary objective of cleaning. Mechanical cleaning is possible because of the difference in specific gravity between the free impurities and the coal, the density of the former being 1.7 to 4.9, while pure coal has a density of about 1.3. Sulphur is present as pyrites, organic compounds, and sulphates, and only part of the pyrites can be removed by cleaning. Phosphorus is usually associated more with bony and impure coal than with clean coal and is, therefore, reduced by washing. Salts, particularly the alkali chlorides, lower the fusion point of the ash, affect coke-oven linings and are troublesome in waste liquors from coking operations.

The preparation of coal starts at the production face in the mine. If loading is done by hand, the miner is required to discard all rock and slate over 3-in. size. If loading is done mechanically (according to the U. S. Bureau of Mines, about 75 per cent of the total bituminous coal mined underground in the United States is being loaded entirely by mechanical means as this is written) no attempt is made to prepare the coal at the face other than to control the tonnage from various sections of the mine if sulphur content of the coal is known to be high or variable.

Since the cleaning problem becomes more difficult the finer the coal, modern practices in extraction and handling employ mining methods for production of the greatest quantity of coarse-size coal.

The cleaning qualities of a particular coal are determined by the **float and sink test**. This test consists in crushing coal to proper size and floating individual samples of it on liquids having densities of 1.30, 1.40, 1.50, 1.60, etc., to determine the weight and character of the material that floats and sinks in each liquid. The proportion of coal, and the ash and sulphur content of the different fractions, provides reasonably complete data on the washability characteristics of a tested coal.

There are two general types of coal cleaning processes: (1) gravity stratification, and (2) nongravity processes. Processes based upon the first type are generally used in this country; nongravity processes have been used extensively in Europe. The processes for cleaning coal may be classified as follows:

A. Gravity separation

1. Wet processes

a. Launder washers

b. Jigs

c. Rising-current classifiers

d. Tables

2. Dry processes

a. Jigs

b. Tables

B. Float-and-sink methods

1. Fine-solids and water flotation

a. Sand

b. Magnetite and other materials

2. Fine-solids and air flotation

C. Froth flotation

A complete description of each of the foregoing processes would be too lengthy for inclusion herein; hence only a brief review will be given of the principles of some of the more important types of processes in use at present. A reference list for further study of this subject is appended to this chapter.

Jigs were probably the earliest type of machine used in the mineral industry to separate materials of different densities. They consist essentially of a box with a perforated base into which the material is placed, and by alternate surges of water upward and downward through the perforations, materials of different specific gravities stratify. Materials having the highest specific gravities remain at the bottom while the lighter material rises. With proper mechanical facilities, a continuous separation is achieved. While jigs are not very efficient in cleaning a mixture of various sizes, they are capable of satisfying some market requirements, and capacities up to 500 tons per hour have been obtained.

The operating principle of a **launder** involves hydraulic stratification or the alluviation of materials of different gravity. The Rheolaveur launder consists of a downwardly inclined flume fitted with compartments spaced at intervals below the flume. Coal and flush water are fed at the high end, and the heavy-gravity material is withdrawn through the compartments. The water and coal having a top size not exceeding 6 inches are fed in at one end of the launder, the first section of which is steeply inclined to give the mixture a high initial velocity. This strong current causes the coal, middlings, and slate to stratify quickly, so that by the time the mixture reaches the flat section, the coal is carried forward while the refuse is definitely retarded. From this point the launder may again be steeply inclined to deliver the flow to a second flat section, finally to make an exit through a chute to dewatering screens. Successively, the heavy-gravity final rejects, including heavy and light middlings are withdrawn from the launder, the last two products being recirculated after withdrawal for the purpose of improving the washing efficiency. The end result is a refuse relatively free of recoverable coal and a coal relatively free of extraneous material. Where the coal has fallen into a middle-gravity classification due to its being laminated with slate or pyrites, it is drawn off, crushed, and freed of these impurities and then rewashed for recovery of the coal. The Rheolaveur launders are capable of cleaning coal of practically any size. Their capacity is variable depending upon the width of the launder and size of the coal to be cleaned. Coarse coal may be treated at rates ranging from 65 to 250 net tons an hour, and fine coal at rates as low as 20 net tons per hour.

With practically all wet-washing systems the water is recirculated. When the water passes through the dewatering screens it contains a considerable amount of small-size coal solids which must be recovered for efficiency reasons. Also, the circulating water must be clarified before it is returned to the cleaning unit. This

clarification is accomplished in various ways, the most important being by the use of the Dorr-type thickener. Settling cones and settling tanks are also used for this purpose. Where the Dorr thickener and settling tanks are used, it is customary to draw off the settlings in the form of a slurry containing 40 per cent to 60 per cent of solids and to further separate the slurry in a vacuum-type filter. The filters deliver a product with approximately 20 per cent moisture.

Upward-current cleaners are somewhat similar to jigs except that a constant current of upward-flowing water carries the coal particles to the discharge, while the falling particles of refuse settle downward through the rising water stream and are removed at a lower level. They are used principally for cleaning anthracite coal and for cleaning a nearly uniform size coal in a single operation. They are capable of cleaning as much as 150 tons of the coarser sizes per hour.

In dense-media classifiers, only a part of the power for separating coal and refuse is supplied by the upward flow of liquid, this separating power being supplemented by using a liquid medium which is heavier than water. The medium employed is a mixture of water and some finely divided solid material, such as sand, magnetite, or barite, which can be separated readily from the washed coal and reused. In the high-density suspension process, the upward flow is discarded entirely, the liquid medium consisting of a mixture which is just dense enough so that the coal floats in it, and the impurities sink. The size of coal has less significance in the efficiency of this process than of those previously described, and material ranging from 1/16 inch to 10 inch can be cleaned in one operation. However, difficulty is encountered in separating the solid material from coal of fine size. Capacities up to 600 tons per hour have been obtained with bituminous coal. The Chance method, which uses a mixture of sand and water, is the most widely used of the heavy-media classifiers in the United States. The Tromp and Barvoys processes, using magnetite and barite respectively as the solid material in the mixture, are used extensively in Europe. In these processes, the specific gravity of the mixture of solid material and water can be varied by changing their proportions to suit the optimum conditions in cleaning. Agitation in the separating cone is supplied by an upward current of water and by mechanical stirring.

A number of high-density solutions, such as those made up of calcium chloride or halogenated hydrocarbons to give the desired specific gravity to the separating medium for cleaning coal, have been used, but to date their application has been limited to the coarser sizes of coal due to the expense of the solution and losses in recovery.

Coal is often cleaned on tables similar to those used in ore dressing. Essentially these tables consist of a slightly inclined rectangular surface having a series of parallel grooves or cleats. The tables are mechanically agitated to permit stratification of the light and heavy material and to cause it to move with the long axis of the table. A current of water is introduced at one side of the table to wash the coal which has settled above the refuse to the discharge edge of the table. The refuse which settles underneath the coal moves longitudinally down the table and is discharged at the end. Tables have been used principally for cleaning coal of the smaller sizes, from dust up to 1-inch.

The disadvantages of water retention associated with wet cleaning have been eliminated by the pneumatic processes. These processes account for about 15 per cent of the coal washed in the United States. They are especially applicable to cleaning a relatively dry coal.

Tables, similar to those described for wet washing, are used where the sizes are under 3/4-inch, except that air currents, rising through a perforated table, are used as the stratification agent rather than water. Jigs and upward-flow processes are also employed. The Stump air-flow cleaner uses air rather than water for classification of material in equipment operating much the same as a jig. A mixture of sand with air, rather than water, to produce a heavy medium for separation is used in some upward-current types of classifiers. In some cases combination wet and dry plants are used to advantage. The restrictions imposed for safety reasons by the U. S. Bureau of Mines, requiring the use of water at underground mining faces to allay coal dust, and the fact that many coals treated need to be cleaned at specific gravities lower than those obtainable by dry air processes, have retarded extensive development in the use of pneumatic methods.

Froth flotation of coal involves agitating fine coal with a mixture of water and a relatively small quantity of some frothing agent. In this process, coal is buoyed to the surface by the froth and removed while refuse settles. Its application has been limited in this country.

The advent of full-seam mechanical coal mining and the increasing need for metallurgical coke of low and uniform ash and sulphur contents has focused attention on the needs for the most efficient types of washers, and also facilities for blending high and low quality coals to obtain the best over-all long-term results.

Carbonization of Coal—The most important use of coal in the steel industry is in the manufacture of coke, which is discussed in detail in Chapter 4. About one-sixth of the total bituminous coal mined in the United States is converted into coke, either in beehive or by-product coke ovens. Of the 72.7 million tons of coke produced in 1950, 66.9 million was by-product and 5.8 million beehive. In 1950, there were 56 active by-product coke plants connected with iron furnaces out of a total of 85 plants, producing 55,987,350 net tons of coke, or 83.8 per cent of the total national by-product coke production.

In recent years, on the average, metallurgical coke produced in by-product ovens has shown an increase in ash and sulphur content above that of former years. An increase in ash and sulphur content of coke affects pig-iron production and economies. The penalties for high and variable ash and sulphur contents in coke in blast-furnace operations are additional slag volume, increased coke consumption, decreased production, and difficulty of furnace control. In addition to the importance of chemical properties, the structural properties (i.e., resistance to shatter, size, crushing strength and bulk density) and possibly the reactivity or combustibility of coke are of paramount importance in coke quality.

The carbonization of coal in by-product ovens entails the production of large amounts of coke-oven gas and tar, important fuels in the steel industry, as well as light oils and various coal chemicals. The yields of gas and tar are largely a matter of the kind of coal used and the temperatures employed in coke manufacture.

Combustion of Solid Fuels—The principal combustion reactions of solid fuels have been given in Section 3 of this chapter, under "Principles of Combustion," and this present discussion will deal with operating factors pertinent to the combustion of solid fuels in steel plants.

The combustion of coke in blast furnaces has been studied by a number of investigators, each of whom has found that combustion takes place in a relatively small space directly in front of each tuyere, as discussed in Chapter 12 on "The Manufacture of Pig Iron."

Coke breeze, produced by screening coke at both the coke plant and blast furnaces, is utilized as a fuel in

steel-plant boiler houses to generate steam. This fuel is burned on chain-grate stokers. Of importance in the combustion of coke breeze on chain-grate stokers is the maintenance of a relatively uniform fuel bed on the grate, 8 to 12 inches thick, to prevent blowholes, and a balanced or slight positive pressure in the furnace at fuel-bed level. The operation of the grate should permit the normal combustion of about 30 pounds of coke breeze per square foot of effective grate area per hour. Chain-grate stokers are particularly adaptable to solid fuels with an ash of low fusion point. The design of front and back arches must take into consideration the fuel to be burned on chain-grate stokers. The arches are utilized to reflect heat and thereby aid ignition on the fuel bed.

Stokers for firing coal have generally been used in steel-plant boilers on units whose capacity is under 100,000 pounds of steam per hour and for units using exclusively a solid fuel. They are often used on boilers to provide flexibility for the adjustment of boiler output to the steam load in plants where there is an insufficient or fluctuating supply of gaseous by-product fuels. The advantage of stokers lies in their ability to control easily the rate of combustion of a solid fuel with efficient use of air. The combustion process on stoker-fired boilers consists essentially in first driving the volatile matter from a continuous supply of fuel, and then oxidizing the carbon in the residue on the stoker. The combustion of the coke-like residue on the grate produces CO_2 and CO . The CO and volatile matter are burned over the grate by secondary air admitted over the fuel bed. The temperature of the fuel bed is affected by the rate of firing and, at the top or hottest part of the bed, varies from about 2250°F at low to 2750°F at high rates. The amount of primary air supplied determines the capacity of stoker-fired furnaces and the effective use of secondary air determines the efficiency of combustion. In well operated and carefully sealed boilers, approximately 20 to 30 per cent excess air will permit combustion of the gases within seven or eight feet above the grate.

Stokers are classified in general according to the travel of the fuel. In an **overfired stoker** the fuel is fed on top of the bed, and in an **underfired** or a **retort stoker** the fuel is fed at the bottom or side of the bed. A **traveling-grate stoker** carries the bed horizontally on the flat upper surface of a conveyor as in a chain-grate stoker. There are a number of modifications of these stoker types. While the fuel bed of a stoker-fired boiler is relatively thin, usually from 4 to 12 inches, compared to a gas-producer bed, similar zones of reaction occur. In over-fired stokers the ash zone is immediately above the grate, followed by the oxidation, reduction and distillation zones. In underfired or retort stokers the distillation of the volatile matter takes place in an oxidizing atmosphere and the volatile products pass through the incandescent residue from combustion rather than through green coal, as in the case of overfired stokers. The normal combustion rates on coal-fired stokers amounts to 30 to 60 pounds of coal per square foot of effective grate area per hour.

Pulverized Coal—The cement industry was the first to use pulverized ("powdered") coal extensively as a fuel. Public utilities and the steel industry began applying pulverized coal on an experimental basis as a boiler fuel about 1917, and by 1935 practically all large boilers (above 100,000 lbs. of steam per hour) in public-utility power stations used this fuel, except for those stations located in the vicinity of oil and natural-gas fields where local fuels were more competitive than coal. Large modern boiler installations in integrated steel plants generally use pulverized coal, either as a standby or as an

auxiliary fuel in conjunction with blast-furnace gas for steam or power generation. Although pulverized coal has been used as a fuel for metallurgical purposes in steel plants, such as in open-hearth, reheating, forge and annealing furnaces, applications have been limited generally to periods of national fuel shortages, such as existed during the first and second World Wars, when the more desirable liquid or gaseous fuels were diverted to other uses and not available.

Pulverized coal offers important combustion advantages over solid fuels and an economic advantage over gaseous and liquid fuels in most sections of the country. Fine particles of coal burned in suspension are capable of developing a highly luminous, high-temperature flame. Coal in this form may be burned normally with less excess of air above theoretical requirements than with a solid fuel, and the rate of heat release from the combustion of pulverized coal is greater than that accomplished with the solid fuel. Coal, when pulverized to the degree common for boiler uses (70 per cent through a 200-mesh screen), has the control flexibility of gaseous and liquid fuels. Practically all ranks of coal, from anthracite to lignite, can be pulverized for combustion and each possesses specific combustion characteristics which largely influence the extent of pulverization.

The ash-disposal problem has been one of the principal deterrents to a more extended use of pulverized coal. In the cement kiln, coal ash is no problem as it is absorbed by the cement in the kiln without adverse effect on the final product. In boilers, the principal difficulty of clogged boiler tubes and deterioration of furnace walls has been overcome by the use of slagging-type furnaces in which the ash in molten form is granulated by water jets at the bottom of the furnace well. The problem of ash contamination resulting from burning fine particles of coal in suspension above a metallic liquid bath or mass of hot steel, damage to refractories from the chemical or physical action of ash, and the clogging of furnace checkers or recuperators from ash accumulation, as well as the normal availability of other fuels, has prevented widespread use of the fuel for metallurgical purposes in steel plants.

Pulverized coal for firing boilers is relatively more modern than stokers. This fuel is used generally on boiler units having a capacity in excess of 100,000 lbs. of steam per hour, or on practically any size of boiler using combination firing with oil or gas. Pulverized coal offers high boiler efficiency, and means for quick regulation of boiler load. The rank of coal pulverized and the extent of pulverization particularly determine the speed of combustion. A high-volatile coal will burn faster than anthracite coal, also one with a lower ash content will burn faster. The process of combustion with pulverized coal is similar to that of lump coal but is of much higher velocity due to the introduction of the particle in suspension in a high-temperature chamber, and the greater surface exposure relative to weight. The release of volatile matter in pulverized coal is practically instantaneous when blown into the furnace, and the speed of combustion of the resulting carbonized particle and volatile gases depends upon the thoroughness with which the pulverized coal has been mixed with air. High combustion temperatures, low ash losses, and low excess air needs (10-20 per cent), with resultant high boiler efficiencies (85 to 90 per cent with good practice), make pulverized coal an ideal boiler fuel. Air for combustion of pulverized fuel is generally preheated, with 10 to 50 per cent of that required introduced ahead of the pulverizer and the balance made up at a point near the burner. This method of introducing the air helps dry

the coal and maintains a non-explosive mix in the pulverized-coal transmission system. The combustion-chamber size for pulverized coal is generally proportioned for a heat-release range of from 20,000 to 100,000 Btu per cu. ft. of combustion space per hour. The differ-

ence in requirements is dependent upon whether pulverized coal is the sole fuel to be used in the chamber, the size of the coal particles, the rank of coal to be pulverized, the ash-slagging temperature of the coal, and the desired temperature for the combustion chamber.

SECTION 6

LIQUID FUELS AND THEIR UTILIZATION

Liquid fuels are essential to many parts of the American transportation system. The movement of passengers and freight by highway and air is dependent upon gasoline, a product of petroleum. The railways of the country are being equipped rapidly with Diesel locomotives powered by fuel oil. Nearly all ocean-going ships are driven by oil, as are the majority of lake and river craft. Liquid fuels have also become of major importance as a source of heat and power in manufacturing plants. The peculiar advantages of petroleum as a source of energy and the available supplies have brought about a phenomenal growth in the petroleum industry. In the period from 1918 to 1950 the consumption of all grades of oil in the United States rose from approximately 450 million to 2,400 million barrels. In 1951, the United States produced somewhat more than 50 per cent of the world's supply of crude petroleum.

Fuel oil, tar, pitch and pitch-tar mix are the principal liquid fuels used in the steel industry. Table 3—XII shows the consumption of fuel oil, tar and pitch for the year 1952.

The liquid fuels consumed annually amount to over 4 million Btu per ton of steel ingots and castings produced. The largest share of this fuel is consumed in melting furnaces. Since melting furnaces require from 3 to 5 million Btu per ton of ingots produced, the significance of liquid fuels in open-hearth practice is apparent.

Tar and pitch are by-products of the manufacture of coke. The virgin tar as it comes from the ovens contains valuable tar-liquor oils which can be extracted and the residue pitch used as a fuel. It is customary to mix virgin tar with this highly viscous residue to provide fluidity for facilitating handling and burning, or to utilize tar in which only the lighter products have been removed by a topping process by which sufficient fluidity is retained. Pitch-tar mixtures and topped tar make available for use as a fuel 78 to 83 per cent of the heat in the virgin tar recovered in the distillation process. The virgin tar produced in the United States for the years 1950 and 1951 amounted to 739,868,767 and 795,311,282 gallons, respectively. Approximately 40 per cent of this (31,300,000 gallons) was used in the steel industry as a fuel in 1950.

The reserves of crude petroleum in this country were estimated at over 25,000,000,000 barrels as of January 1, 1951, and during the prior year (1950) the annual pro-

duction was nearly 1,950,000,000 barrels. Since 1939 there has been a downward trend in new discoveries, and unless new national reserves are found in excess of consumption, it will be necessary to obtain supplies from foreign countries.

Origin, Composition and Distribution of Petroleum—Classified according to their origins, three main types of rocks make up the outer crust of the earth: igneous, sedimentary and metamorphic rocks. **Igneous rocks** are formed from **magma**, a molten (liquid or pasty) rock material originating at high pressures and temperatures within the earth. Lava is magma that reaches the surface in the liquid or pasty state. Very commonly, the magma cools and solidifies before reaching the surface. In any case, when the molten material cools sufficiently to become solid, igneous rocks are the result. If cooling is slow, the rocks will be crystalline (granite, for example); but if the cooling is rapid, the rocks will be not crystalline but glassy in nature (obsidian, for example). Because of the nature of their origin and their usually dense, non-porous structures, igneous rocks are never hosts to petroleum deposits.

Sedimentary rocks are formed from eroded particles of rocks and soil, carried away by wind or water (and sometimes glacial action) and deposited in seas, lakes, valleys and deltas in relatively even, sometimes very thick, beds or strata (sandstones and shales are formed from deposits of this type). Other types of stratified deposits may be formed by evaporation of land-locked seas (beds of rock salt), by accumulation of the mineral remains of animals (composed chiefly of calcium carbonate, which is the principal constituent of limestone), or by chemical precipitation (gypsum and some limestones originate in this manner). The beds of sand, silt, clay, calcium carbonate or whatever eventually are covered by other sedimentary deposits, sometimes to very great depths. With the passage of long periods of time, pressure of the overlying strata, heat, cementation by chemical means, earth movements, or a combination of these or other agencies, the strata are consolidated into sedimentary rocks, typified by the few mentioned parenthetically earlier. *Petroleum occurs almost entirely in sedimentary rock formations*, principally sandstones and limestones, under certain ideal conditions to be described later.

Metamorphic rocks originally were sedimentary or

A. STRATIGRAPHIC TRAP.—In the stratigraphic trap, the producing formation gradually pinches out and disappears up the structure. An impervious layer is deposited on top of the sand, thus forming a cap rock. The solid black section represents petroleum accumulated below the cap rock.

B. ANTICLINES.—In an anticlinal structure, the rocks comprising the crust of the earth are folded upward. The oil and gas are usually found on the crest of an anticlinal structure. An impervious cap rock must be present to seal the reservoir and prevent the escape of the gas and oil into higher layers. This cap rock, in one form or another must be present in all reservoirs to contain the oil and gas within the structure.

C. SALT DOMES.—The salt dome is believed to be the result of the intrusion of large masses of salt into the sediments where they are found. This intrusion creates an upward pressure and results in the doming of the overlying sedimentary rocks. In this type of structure, petroleum accumulates within the upturned porous beds about the summit and flanks of the salt core, as indicated by the solid black sections.

D. FAULTS.—A fault is a structural closure caused by the fracturing of the crustal rocks during earth movements. In the process of folding, a reservoir for oil may be formed when a porous rock is brought into contact with an impervious layer, thus forming a trap.

FIG. 3—3. Schematic representation of four geologic structures associated with the underground accumulation of petroleum through natural agencies. From "Fundamentals of Petroleum," NAVPERS 10883, Superintendent of Documents, U. S. Government Printing Office, Washington, D.C.

igneous rocks. Their composition, constitution or structure have been changed through the single or combined action of natural forces such as heat, pressure, or other agencies. Marble, for example, is metamorphosed limestone.

The organic theory of the origin of petroleum, generally accepted by geologists, is that petroleum has been derived from either animal or vegetable matter, or both, by a process of slow distillation, after its burial under beds of sediments. There is evidence to indicate that the animal and vegetable matter was of marine origin; such evidence includes the association of brines with oil, the

visible oily coating on seaweeds found in certain localities, and the optical phenomenon of light polarization by oils similar to that of substances found in certain plants and animals and which is not shown by inorganically synthesized petroleum. The accumulation of the matter from which petroleum has been derived, its burial by sedimentary material, and the action of pressure and heat to cause distillation, has resulted in petroleum formation in many parts of the world. Geological studies indicate that petroleum was not formed in the pools in which it is found, but that the action of water pressing against oil formations caused the petroleum to flow, over

a period of many years, through porous beds or strata to points of accumulation. Pools of oil occur in "traps" in sedimentary rocks such as sandstone or limestone. These traps may be formed in various ways, a few of which are illustrated schematically in Figure 3-3. Essentially, such traps are formed by an impervious layer which prevents upward migration of the petroleum to any further extent. The oil is obtained by drilling wells into these zones of accumulation. The well is encased in a steel pipe through which it is often customary to run a number of smaller pipes to bring the product to the surface.

Crude petroleum is a liquid containing a complex mixture of solid, liquid and gaseous hydrocarbons. The solid hydrocarbons are in solution and the liquid is at least partly saturated with gases (methane, ethane, etc.). The elementary composition of American crude oils from representative fields covers the following ranges:

Carbon	84 to 87
Hydrogen	11.5 to 14.0
Sulphur	0.05 to 1.75
Nitrogen	0.10 to 1.70

Ordinary crude petroleum is brownish-green to black in color with a specific gravity from about 0.810 to 0.985, and an ash content of 0.01 to 0.05 per cent.

The principal constituents in crude oil are the paraffin (C_nH_{2n+2}), naphthene (C_nH_{2n}), and aromatic (C_nH_{2n-6}) series of hydrocarbons, and asphaltic compounds. In paraffin-base crudes, such as found in Pennsylvania, the asphaltic content is low, only traces of sulphur and nitrogen are found, and the specific gravity averages about 0.810. In mixed-base crudes which have a lower content of paraffins and a higher content of naphthenes than the paraffin-base crudes, the content of asphaltic compounds is higher, the sulphur content usually is under 0.4 per cent and the paraffin-wax content is generally high. Mixed-base crudes occur in the mid-continent region. The naphthene-base crudes contain a high percentage of naphthenes, very little paraffin wax, and have a relatively high specific gravity. They occur in the central, south-central and south-western areas of the United States. Light naphthene-base crudes contain a low proportion of asphalt, compared to reverse proportions in heavy naphthene-base crudes. The sulphur content varies widely. The aromatic crudes, which occur chiefly in California, generally have a high asphaltic-compound content, sulphur content varying from 0.1 to 4.13 per cent and a relatively high nitrogen content. The specific gravity is often fairly low and the presence of wax widespread, although some crudes of this class are free of wax.

Crude oil is delivered to the refineries by rail, inland and intercoastal waterways, in specially constructed tanks, and by pipeline. In 1915 there were less than 20,000 miles of crude-oil trunk lines, which had been expanded in 1950 to nearly 65,000 miles to handle more than 86 billion ton-miles of crude oil and nearly 14,000,000 ton-miles of refined oil.

Grades of Petroleum Used as Fuels—Fuel oils may be classified generally as: (1) raw or natural crude petroleum, (2) distillate fuel oils, (3) residual fuel oils, and (4) blended oils. The increasing demand for gasoline and other petroleum products makes it very undesirable that crude petroleum as obtained from the wells be used for fuel. Besides, gasoline in a fuel oil is dangerous on account of the increased danger of explosions its presence entails. By the older methods of refining, the products from many of the oil refineries west of the Mississippi River were gasoline, naphtha, kerosene and fuel

oil, while eastern refineries usually carried the fractionation of oil much further, their output being such products as gasoline, benzene, naphtha, kerosene, light machine oil, automobile oils, cylinder oils, paraffin wax and tar, pitch, or coke. Recent improvements in thermal cracking at both high and low pressure and the use of catalytic conversion processes have enabled refiners to convert more of the petroleum to gasoline and to produce lubricants from western petroleum relatively high in asphalt.

Distillate fuel oils consist of the fractions distilled intermediate between kerosene and lubricating oils. Residual fuel oils are the viscous residual products remaining after the more volatile hydrocarbons have been driven off in the refining process. Blended oils are mixtures of any or all of the other three classes of fuel oils.

Properties and Specifications of Liquid Fuels—Before discussing the more important properties and specifications of fuel oil, some of the common terms will be reviewed.

Specific gravity is the ratio of the weight of a volume of a body to the weight of an equal volume of some standard substance. In the case of liquids, the standard is water. **Baumé gravity** is an arbitrary scale for measuring the density of a liquid, the unit being called "Baumé degree." Its relation to specific gravity is shown by the formula:

$$Be^{\circ} = \frac{140}{Sp. Gr.} - 130 \text{ (for liquids lighter than water)}$$

For example, the Baumé hydrometer will read 10° Bé in pure water, when the specific gravity scale reads 1.000. The American Petroleum Institute (API) Gravity is a modification of the Baumé scale for light liquids. API gravities are always reported at 60° F. The relation between API gravity and specific gravity is:

$$^{\circ}API = \frac{141.5}{Sp. Gr.} - 131.5$$

The greater the degrees Baumé or API, the lighter the fluid. There are about 90 API degrees between the heaviest and lightest oils which, therefore, makes this scale valuable for determining differences between the density of various oils.

Flash point is the lowest temperature at which, under definite specified conditions, a liquid fuel vaporizes rapidly enough to form above its surface an air and vapor mixture which gives a flash or slight explosion when ignited by a small flame. It is an indication of the ease of combustion or of the fire hazard in handling or using oil.

Pour point is the lowest temperature at which oil will pour or flow when chilled without disturbance under specified conditions.

Viscosity is the property of liquids that causes them to resist instantaneous change of shape or the arrangement of their parts due to internal friction. Since this property has a direct relation to resistance of flow in fuel-oil pipe systems and to atomization, it is an important specification. **Absolute viscosity** is a measure of internal fluid friction. It is expressed in the English system as pounds per second per foot and is the force which will move one square foot of a plane surface with a speed of one foot per second relative to another plane surface from which it is separated by a layer of the liquid one foot thick. The viscosity of a fluid relative to water at 68° F is the ratio of its absolute viscosity to that of water at 68° F (both absolute viscosities must be in the same units). This relation is called **relative viscosity**. The absolute viscosity of water at 68° F is 0.000672 lbs. per sec. per ft. or 0.0100 gms. per sec. per cm. which is equal to

Table 3—XIII. Properties of Typical Liquid Fuels

0.0100 poises or 1.00 centipoise. The viscosity of all liquids decreases with increasing temperature and ASTM viscosity determinations are made at oil temperatures of 100° F, 122° F, 130° F and 210° F, and are often expressed as Saybolt Universal at 100° F or Saybolt Furol at 122° F. The terms "Saybolt Universal" and "Saybolt Furol" represent the type of instrument used in making the viscosity determinations. Viscosity measurements made by either may be interconverted by the use of tables.

Reid Vapor Pressure is a test for the vapor pressure of gasoline at 100° F. It shows the tendency of gasoline to generate vapor bubbles and is expressed in pounds per square inch absolute.

Octane number is the anti-knock rating of gasoline. The rating is made by matching the fuel in a test engine with a mixture of normal heptane, which detonates very easily and has an octane rating of zero, and iso-octane, which has exceptionally high anti-knock characteristics and is rated at 100. A fuel knock that matches a mixture of say 60 per cent octane and 40 per cent heptane would have an octane rating or number of 60. **Cetane number** is used to show the ignition quality of Diesel oils. The rating is based on a scale resembling those of octane numbers by matching the ignition delay of the fuel against blends of cetane, a fast-burning paraffin, and methyl naphthalene, a slow-burning aromatic material.

The A.S.T.M. has developed a table for grading fuel oils, consisting of six grades. According to this classification, heating oils generally used for domestic and small industrial heating furnaces comprise Grades 1, 2 and 3. Grades 5 and 6 correspond to **Bunker "B"** and **Bunker "C"** fuel oils, respectively, which are used extensively in the steel industry. **Bunker "B"** fuel oil is usually cracking-still tar and Grade 6, or **Bunker "C"** fuel oil, a straight-run or cracked residual, or a mixture of residual and cracking-still tar blended to reduce the viscosity to that required by the consumer.

All grades of fuel oil are normally sold to meet specifications mutually satisfactory to buyer and seller. A typical specification of **Bunker "C"** fuel oil for use in open-hearth furnaces is as follows:

Gravity—API (60° F)13.0 to 16.0
Flash point (closed cup)150° F minimum
Btu per gallon150,000 minimum
Sulphur0.75 to 1.00 maximum
Viscosity at 122° F100 secs. Saybolt Furol
Water and sediment (% by vol.) .1% maximum

The yield of tar produced in by-product coke ovens by

high-temperature distillation between 1832 and 2012° F (1000 to 1100° C) differs within very wide limits according to the kind of bituminous coal coked, and to the temperature, coking time, and design of oven employed in the process. Virgin tar as produced in the by-product ovens consists essentially of tar acids, neutral oils which are principally aromatic hydrocarbons, and a residuo pitch.

The residue pitch from the distillation of tar is highly viscous or brittle. Pitch contains a substantial percentage of free carbon and some high-boiling and complex organic chemicals. The properties of a typical pitch-tar mix and **Bunker "C"** fuel oil are shown in Table 3—XIII.

The viscosity of liquid fuels decreases with temperature increase. The range of typical samples of virgin tar, pitch-tar mixtures and topped tar is as follows:

Fuel	Test Temp. (°F)	Viscosity in Sec., Saybolt Universal
Virgin Tar	175	{ 189.4 max. 73.3 min. 109.4 avg.
Pitch-Tar Mix	175	{ 1940 max. 181 min. 946.1 avg.
Pitch-Tar Mix	210	{ 687 max. 97 min. 561.7 avg.
Topped Tar	200	{ 700 max. 550 min. 600 avg.

Combustion of Liquid Fuels—The combustion of liquid fuel usually is obtained by atomizing the fuel. Atomization breaks up the fuel into fine, mist-like globules, thus permitting an increased area for intimate contact between the air supplied for combustion and the fuel. The chemistry of combustion of liquid fuels is complex. The small particles of fuel either vaporize to form gaseous hydrocarbons which burn to CO₂ and H₂O through a chain of reactions, or the fuel cracks to form carbon (soot) and hydrogen which also burn with complete combustion to CO₂ and H₂O. Both of these condi-

tions normally occur in the combustion of liquid fuels. The first condition predominates with good atomization and proper mixing with sufficient air. A deficiency of air or poor atomization will cause smoke. For large furnaces, such as open hearths and heating furnaces, the atomizing agent is usually steam at a pressure anywhere between 60 and 125 pounds per square inch gage. The steam consumed in atomization varies from 0.3 to 0.7 pounds per pound of fuel. When liquid fuels are used in smaller furnaces, atomization usually is procured by compressed air or by mechanical action. The character of a liquid-fuel flame, that is, its shape, size and luminosity, may be altered with a fixed burner design by changing the degree of atomization which is controlled by the steam pressure. Liquid fuels normally are burned in steel plants to produce a highly luminous flame at an intensity of flame propagation intermediate between that generally secured with coke-oven gas and that with natural gas.

Liquid fuels usually are preferred above all other fuels for use in open-hearth furnaces because they permit better control of flame direction and, because of their high calorific value, control of flame temperature and luminosity.

The amount of air required to burn liquid fuels depends upon the chemical composition of the particular fuel. Bunker "C" fuel oil requires approximately 180 cu. ft. of dry air per pound of oil for perfect combustion, and tar-pitch approximately 158 cu. ft. From the ultimate analysis of a liquid fuel, the theoretical air requirements and products of combustion may be calculated, as explained in Section 3 under "Combustion Calculations." The composition and properties of tar-pitch are given in Table 3—XIII, shown earlier.

Liquid-Fuel Burners—There are many different designs of burners for liquid fuels. Burners designed for atomization by steam or air may be classified into two general types, the inside mixing and the outside mixing. In the inside-mixing type the fuel and atomizing agent are mixed inside the burner or burner system, while in

the outside-mixing type the two fluids meet immediately outside the burner tip. In open-hearth furnaces and large reheating furnaces the inside-mixing type is used. The inside-mixing type is sometimes classified as an emulsion type or a nozzle-mix type of burner. In the emulsion type the mixing is performed at a point several feet from the burner tip, while in the nozzle-mix type the two fluids meet inside the burner but very close to the burner tip. In the latter type, mixing probably takes place both inside the burner and as the stream enters the furnace.

Liquid-fuel burners used in open-hearth furnaces are water cooled due to port end design; those in reheating, forge and annealing furnaces seldom require water cooling.

The handling of liquid fuels at consuming plants requires a system for their transportation, storage and conditioning. Where liquid fuels are received by tank car, a system of receiving basins, unloading pumps, strainers and storage tanks generally is required. The storage tanks must be of ample size to meet fuel demands between deliveries and should be provided with heaters to maintain proper fluidity for flow through pipe lines to the system pressure pumps. Pressure pumps are used to deliver the liquid fuel through a pipe system to the point of consumption. Where there are a number of consuming units being served from a common fuel-storage system, the pipe feeder line is designed in the form of a loop through which the fuel flows at constant pressure and temperature. The various units tap into this loop. The fuel-oil lines are lagged and provided with tracer steam lines to maintain uniform fluidity throughout the system and to provide fuel at the burners at the proper viscosity for atomization. The temperature at which liquid fuel is delivered to the burners varies with the character of the fuel and burner design. Where pitch is used, a temperature as high as 300° F in the lines is sometimes required. A temperature level usually somewhere between 200° F and 250° F is maintained for pitch-tar mixtures, and 150° F to 200° F for Bunker "C" fuel oil.

SECTION 7

GASEOUS FUELS AND THEIR UTILIZATION

The availability of natural gas in so many sections of this country has had a profound influence upon our industrial progress and comfort. It was first used as an illuminating gas at Fredonia, New York, in 1824. The discovery of new fields and the installation of pipe lines to consuming centers led to increasing demands, as the convenience, cleanliness, and general utility of this form of fuel became better known. The initial use of natural gas for steel manufacture was at a rolling mill plant at Leechburg, Pa., in 1874. A well in this area permitted exclusive use of natural gas for puddling, heating, and steam generation for a period of six months. Since 1932 there has been an accelerated demand for natural gas.

In 1950, for example, 6,281 billion cubic feet of natural gas were produced. To meet this demand, the gas industry had installed some 265,000 miles of natural-gas pipe lines by the close of 1950.

Producer gas was the first gaseous fuel successfully utilized by the iron and steel industry. This gas permitted the early experimentation in regeneration, and the utilization of this principle started a new era of steel manufacturing. The advantages of preheated gas and air were so clearly indicated in 1861 that producer gas rapidly became the major fuel utilized by open-hearth furnaces

and maintained its position for almost sixty years, or until about 1920, when by-product coke plants, supplying coke-oven gas and tar, began to challenge this leadership.

Blast-furnace gas utilization by the iron and steel industry probably should rank first historically, although its adoption by the industry was slower than in the case of producer gas. The sensible heat in the blast-furnace top gases was first utilized in 1832 to transfer heat to the cold blast. Originally, this heat exchanger was mounted on the furnace top. In 1845, the first attempts were made to make use of its heat of combustion, but history indicates that the burning of blast-furnace gas was not successful until 1857. It is probable that progress in the utilization of blast-furnace gas was delayed by its dust content, the problems of cleaning and handling, and the low cost of solid fuel. Increasing cost of other fuels and competition forced its use, and by the turn of this century, blast-furnace gas had become one of the major fuels of the iron and steel industry. In 1951, the blast-furnace gas produced and consumed amounted to nearly 28 million tons of coal equivalent.

The initial use of by-product coke-oven gas in the iron and steel industry was at the Cambria Steel Company,

Johnstown, Pa., in 1894. This installation was followed by only a few by-product coke-plant additions until a shortage of transportation facilities and the rising price of coal and natural gas during the first World War accelerated installations throughout the steel industry. The utilization of coke-oven gas has been very profitable as it reduced the purchase of outside fuels. It is estimated that plants operating steel-making furnaces used 371,476,712,000 cubic feet of coke-oven gas as fuel in 1950.

Natural Gas—Natural gas and petroleum are related closely in their chemical composition and in geographical distribution. Both are made up predominately of hydrocarbons. Petroleum rarely is free of natural gas, and the same fields usually produce both fuels. When natural gas exists indigenous to an oil stratum and its production is incidental to that of oil, it is called **casinghead gas**. Gas found in a field is usually under pressure which diminishes with extended use or, sometimes, from the presence of too many other wells. The life of a well varies from a few months to twenty years. The depth of wells varies from 250 to 4000 or more feet. Rocks bearing gas are sandstones, limestones, conglomerates, and shales—never igneous rocks. Natural gas is derived from the remains of marine animal and plant life—in theory, the same as described previously for petroleum.

Natural gas as found is usually of singular purity and is composed principally of the lower gaseous hydrocarbons of the paraffin series, methane and ethane, some of the heavier liquefiable hydrocarbons (which are recovered as **casinghead gasoline** or sold in bottled form as butane, propane, pentane, etc.) and a small amount of nitrogen or carbon dioxide. Some natural gases contain small quantities of helium. Occasionally, wells are found in which the gas contains hydrogen sulphide and organic sulphur vapors. **Sour gas** is defined as a natural gas which contains in excess of $1\frac{1}{2}$ grains of hydrogen sulphide or 30 grains of total sulphur per 100 cu. ft. It is fortunate, however, that by far the greater part of natural gas available in this country is practically sulphur-free.

There are a number of great gas fields in this country; viz., the Appalachian, the Lima-Indiana, Illinois, Mid-Continent, Gulf, and California. Due to the increasing customer demand, exhaustion of wells, and the inability of the older local fields to adequately meet the demand, a number of the fields have been linked by pipe lines. Gas from the extensive Texas oil fields, which previously

had been allowed to escape on account of lack of pipe lines to carry the excess to more distant consuming centers, now is being utilized.

The principal constituent of natural gas is methane, CH_4 . Since natural gas contains from 60 to 100 per cent of CH_4 by volume, the characteristics of methane gas, which were shown in Section 3, largely dominate the parent gas. Comparing methane with the other principal combustible gases, it will be noted that it has a low rate of flame propagation, a high ignition temperature, and a narrow explosive range. Methane, as well as all other hydrocarbons (of which it is the lowest member), burns with a luminous flame.

Typical compositions of natural gas are presented in Table 3—XIV.

The iron and steel industry consumed 208,989 million cubic feet of natural gas in 1952, 206,797 million cubic feet in 1951, and 203,852 million cubic feet in 1950.

Manufactured Gases—The four most important manufactured gases are **producer gas**, **water gas**, **oil gas**, and so-called **bottled gases**. All are used domestically and industrially.

Producer gas may be made from coke, anthracite coal, or bituminous coal. When made from bituminous coal, the raw, uncleaned gas contains tarry deposits which render it unsuitable for pipe-line transmission. Hot, raw producer gas has wide successful application in industrial plants, principally those of the steel, ceramic, and glass industries, but is never used for domestic service. Cleaned, cooled and washed producer gas is produced by public utilities for both domestic and industrial use.

Water gas is made usually from coke or anthracite coal. It is relatively clean compared to producer gas and is used much more extensively for domestic purposes. It has gained great importance in the chemical industry in the past decade as a base for the production of synthetic organic chemicals. Water gas is often called **blue gas** and when enriched with cracked fuel oil it is called **carburetted water gas**.

Oil gas is a combination of cracked petroleum and water gas made by passing oil and steam through hot refractory checker work. Oil gas is commercially important in localities where coal or coke is expensive and oil cheap.

Bottled gases are liquefied petroleum gases. They have become commercially important because of the concentration of fuel energy in liquid form which may be

Table 3—XIV. Typical Composition of Natural Gas in Various Districts

Constituents	Districts

Net Heating Value— Btu/cu. ft.	904	1021	1009	971	879

converted easily into a gas. They are distributed for household use in steel cylinders called "bottles" and in tank cars or trucks for industrial purposes. They are sometimes sold under various trade names but are composed mainly of butane, propane, and pentane. A steel cylinder of propane as sold for domestic purposes contains approximately 21,640 Btu per pound of liquid gas.

Manufacture of Producer Gas—Producer gas is manufactured by blowing an insufficient supply of air for complete combustion, with or without the admixture of steam, through a thick, hot, solid-fuel bed. A large proportion of the original heating value of the solid fuel is recovered in the potential heat of carbon monoxide, hydrogen, tarry vapors, and some hydrocarbons, and in the sensible heat of the composite gas which also contains carbon dioxide and nitrogen. When the gas is cleaned, the sensible heat of the gases and the potential heat of the tar vapors is lost. Originally, gas producers were blown only with air, and the gas produced had a heating value of only about 110 Btu per cu. ft. There was trouble with excessive clinker formation due to the exothermic reaction between the oxygen in the air and the carbon in the coal, and a large sensible-heat loss occurred in cleaning.

The basic reactions in an air-blown producer are:

Theoretically, air-blown producers may have 70 per cent gasification efficiency if all the carbon is converted to carbon monoxide (CO). The other 30 per cent is lost when the hot gases are cooled. If all the carbon is converted to CO, the gas would have a heating value of 112 Btu per cu. ft. The introduction of steam with the air, now the general practice, permits generating a gas of higher Btu value (130 to 190), reduces the temperature of the hot zones in the producer on account of the endothermic reaction between steam and hot carbon, and reduces the temperature of the gases leaving the producer.

The thickness and temperature of the zones, the velocity at which the gases move through them, the relation of the volume and ratio of the air and steam in the blast to the coal consumed, gas channeling, and the character of the coal, determine the gas composition and the optimum producer efficiency.

Two typical modern gas producers are shown in Figures 3-4 and 3-5. Figure 3-4 is a cross section of a modern Morgan Construction Company gas producer. The coal feed is regulated by temperature of the outlet gas or by a combination of the temperature reading and the rate of flow of air to the producer, which is metered for that purpose. Temperature of air blast is controlled automatically to maintain a constant weight of steam and air ratio entering the producer in order to maintain uniform firing conditions.

Figure 3-5 is a cross section of a modern Wellman mechanical gas producer equipped with bell-type feed. The producer is designed for application of modern controls for quantity and temperature of gas delivery. An important feature is its mechanically driven, oscillating poker. Air is delivered to the producer by a steam-driven turbo blower.

As shown by Figures 3-4 and 3-5, producers are constructed of steel plates and castings, the parts exposed to high temperatures being lined with refractories or water-cooled. They are made in different sizes and dimensions are varied accordingly. Each producer consists essentially of two separate parts, a combustion chamber and ash pan which are mounted upon rollers

FIG. 3-4. Cross-section of a modern Morgan Construction Company gas producer.

so as to move at a speed of about 1/10 r.p.m., and a top which is stationary and held in place by steel supports. The body portion is lined with best quality firebrick and is constructed to provide water seals at both top and bottom, the top seal to prevent escape of gas and the bottom seal to provide a means of removing the ash formed. Removal of the ash is accomplished by constructing the bottom parts so as to deflect the ash toward the outer periphery of the pan and by providing a scoop or plow to lift the ash out of the pan at certain intervals as required. The top of the machine is water-cooled and contains the openings for the introduction of the fuel, the gas outlet, two or more observation holes, and an opening for the insertion of a poker or a fuel leveler. Some means of keeping the fuel bed at a uniform depth and of distributing or leveling the raw coal is essential, but de-

FIG. 3-5. Cross-section of a modern Wellman mechanical gas producer with bell-type feed.

sign differs as to the method, some using agitation with a poker and others merely a leveler that leaves the fuel bed undisturbed. An essential part of the producer is the blower which is built into the bottom. It serves as a means for introducing the air and steam required for the partial combustion of the fuel and for distributing these so as to obtain uniform combustion over the entire bottom of the fuel bed. There are two types of blowers: the steam-jet or injector type, and the turbo blower. In the former, steam is the only propelling agent, while in the latter, a small steam turbine is directly connected to a blower which forces the air and exhaust steam from the turbine into the producer. The steam-jet type is the cheapest to operate, but formerly it gave poor control because of condensation. Improvements in jets have overcome many of their drawbacks. Supplementary equipment required for efficient operation of the machine include: (1) a boiler to supply steam; (2) electric motors to rotate the machine, operate the fuel feed, and the poker, if the machine is so equipped; (3) a bin located directly above the producer for the storage of the fuel; and (4) a dust catcher and shut-off valve, built adjacent to the machine, to collect dust and soot carried out of the producer with the gas.

The gasification rate of producers varies. Hand-poked machines gasify 10 to 15 lbs. of coal per sq. ft. of fuel bed area per hour. Modern mechanically-poked machines will gasify 50 to 75 lbs. per sq. ft. per hour with good bituminous coals, and rates as high as 90 lbs. have been obtained. The gasification rate with coke breeze is about half that of bituminous coal. The air blown per pound of fuel varies from 45 to 53 cu. ft. depending upon the grade of fuel; about 52 cu. ft. is blown for low-ash high-volatile coal. The steam used per pound of fuel varies from 0.17 to 0.40 lb. depending upon the amount and fusion point of the ash, and is about 0.20 lb. for a high-volatile coal of low ash content with a high ash-fusion point. The efficiency of conversion, per cent total calorific value of fuel recovered, is 88 to 90 per cent when raw gas is consumed hot, and 65 to 80 per cent when the gas is cooled and cleaned.

Table 3—XV gives the composition of clean producer gas made from various fuels in a well-operated updraft producer.

The gross heating value of raw producer gas, including tar, made from a high-volatile coal, 8 per cent ash, is 170 to 190 Btu per cubic foot.

Producer gas has a very low rate of flame propagation due to the relatively large amount of inert gases, N_2 and CO_2 , it contains. The hot gas, containing tar, burns with a luminous flame; the cold gas is only slightly luminous, while it is non-luminous if made from anthracite coal or coke. Producer gas is a relatively heavy gas and has a wide explosive range. The theoretical flame temperature is low, approximately $3175^\circ F$, and the gas generally is preheated when utilized in steel-plant processes.

Manufacture of Water Gas—Water gas or blue gas is generated by blowing steam through an incandescent bed of carbon. The gas forming reactions are primarily:

Since both of these reactions are endothermic, the temperature of the bed of carbon through which the steam is blown would be lowered quickly to a point where no reaction would occur, if proper control was not provided. The temperature of a bed of hot carbon may be increased by blowing air through it, causing the two basic exothermic reactions:

By controlling the time during which air is blown, the temperature level of the bed can be controlled and the effect of the second reaction, which consumes more carbon and generates less heat, is minimized. The air blow raises the temperature level of the bed, and the gases formed during this part of the process pass through a stack to the outside air. The steam run lowers the temperature level of the bed and generates water gas which is collected by passing the gases through outlets to a gas holder, the reservoir for distribution. The character of the gas formed and the amount of steam decomposed during the steam run are largely functions of the bed temperature and thickness, and velocity of gases through the bed. In order to maintain a practical limitation to the rise and fall of the temperature level, the length of each cycle is of short duration, usually from 2 to 6 minutes. The thickness of the fuel bed is maintained by charging fresh fuel periodically and removing ash from fuel spent in the process. Charging usually is done every 45 to 75 minutes and the ash removed every 6 to 8 hours. The velocity of the gases is controlled by the rate of steam input and fuel sizing. In order to maintain as nearly uni-

Table 3—XV. Composition of Clean Producer Gas^u

form temperature as possible in the fuel bed (about 1650° F) and thereby to secure the optimum gas yield and least trouble from ash clinkers, the steam run during which water gas is produced, also called the gas run, is divided into three distinct periods, known as the up-run, the down-run, and the final up-run. These terms designate the direction of the steam-gas movement. In the up-run the steam is admitted below the fuel bed and taken off at outlets above the bed. The down-run is the exact opposite. A typical four-minute water-gas cycle is as follows:

Air Blow		90 seconds—13,000 cu. ft. of air per min. (100–150 c.f.m. per sq. ft. of grate area)
Steam Run	Up-run	44 seconds—175 lb. steam per minute
	Down-run	90 seconds—200 lb. steam per minute
	Up-run	16 seconds—175 lb. steam per minute
	Total	240 seconds

During the air blow period of each cycle, a hot, lean producer gas is formed. A part of this gas sometimes is permitted to dilute the steam-run gas. The latter part of the air blow generates a gas generally high in CO, and is the most efficient period in which to collect this gas. Normally, however, all of the gas made during the air blow is passed through a separate chamber containing refractory checker work and the CO in the gas burned with air diverted from the generator to this chamber. The checkers absorb some of the heat of the spent gases as they pass to the stack. The down-run steam sometimes is passed through the checker chamber before entering the generator to recover the stored heat. Heat in a similar chamber is used for cracking fuel oil when carburetted water gas is made.

The division of each cycle into definite periods requires an elaborate system of valving to direct properly the flow of air, steam and gases, the mixing of which would lead to dilution and, in some cases, to serious explosions. The sequence and time in which the large number of valves must be opened and closed are controlled automatically, the valves themselves being operated either electrically or hydraulically in response to the controls. Since cycles are frequently changed as conditions warrant, the controls are designed for easy alterations to the timing.

While coke generally is used as the fuel in the production of water gas because of its high carbon content and cleanliness, anthracite and bituminous coal and mixtures of coal and coke also have been used successfully, but with some sacrifice in over-all operating efficiency.

Water gas burns with a clear blue flame; hence, the name "blue gas." It is used in a number of chemical processes to supply a basic gas for synthetic processes, but it is not suitable for distribution as a domestic fuel unless it has been enriched with cracked fuel oil, when it is called carburetted water gas.

Water gas made from coke burns with a non-luminous flame. Carburetted water gas burns with a highly luminous flame. Both gases have a high rate of flame propagation. The speed of combustion for water gas exceeds that of any other extensively used fuel gas; that for carburetted water gas is practically the same as for coke-oven gas. Water gas has a slightly lower specific gravity than natural gas, but is somewhat heavier than coke-oven gas. Carburetted water gas is heavier than natural gas but lighter than producer gas. The theoretical flame temperature of both blue and carburetted water gas is very high, respectively about 3670 and 3725° F, exceeding that of all other industrial fuel gases commonly used. Both gases have a relatively wide explosive range.

Special Gas Processes—Studies and investigations in

the art of gasification have been under way in the United States for a number of years. The German demand for self-sufficiency prior to and during the second World War led to developments of the water-gas machine which first made possible continuous gasification, and later the manufacture of a gas containing methane. Technical advances in the manufacture of cheap oxygen contributed largely to these developments. The first step towards improvements in fuel-gas manufacture eliminated the disadvantage of cyclic operation and the second, the necessity for carbureting water gas. Continuous gasification was accomplished in the **Winkler Process** by passing the proper mixture of steam and oxygen through a fuel bed to compensate for the endothermic reaction, $C + H_2O$, with the exothermic reaction, $C + O_2$, thereby maintaining a fixed temperature in the fuel bed.

The **Lurgi Process**, developed in 1936, produces a rich water gas containing CH₄. A mixture of steam and oxygen at 20 atmospheres pressure (steam at 900° F) is introduced through the hollow shaft of a rotating grate and passes through the ash bed into a fixed fuel bed, which is at a temperature of 2150° F, where the fuel is gasified. Fuel is charged intermittently into a hopper immediately above the generator proper. A foot valve between the hopper and generator locks the high pressure in the generator during charging. After filling the hopper, fuel is fed continuously into the generator chamber. A plow directs ash through the grate into a small compartment in the lower portion of the generator, and from there the ash is removed continuously by a revolving scraper into an outside ash hopper.

By-Product Gaseous Fuels—The two major by-product gaseous fuels are blast-furnace and coke-oven gases. A number of other unavoidable gaseous fuels are created by regular manufacturing processes. Some of these are of minor economic consequence, but the majority are useful and generally utilized at the plant where they are produced. An exception is oil-refinery gas which is sometimes piped and marketed to industries adjacent to refineries. The calorific value and flame characteristics of by-product gases have wide ranges. Blast-furnace gas has probably the lowest heat content of any, and oil refinery gas the highest, respectively 90 and 1850 Btu per cubic foot, although both vary from these values.

Blast-furnace gas is a by-product of the iron blast furnace. The paramount objective in blast-furnace operation is to produce iron of a specified quality, economically; the fact that usable gas issues from the top of the furnace is merely a fortunate attendant circumstance. When air enters the tuyeres (see Chapter 12 on "The Manufacture of Pig Iron") its oxygen reacts with the coke. The resulting gas passes up through the shaft of the furnace which has been charged with coke, ore, and limestone, and after a number of chemical reactions and a travel of some 80 feet, issues as a heated, dust-laden, lean, combustible gas. The annual volume production of this gas is greater than that of any other gaseous fuel. Four to five tons of blast-furnace gas are generated per ton of pig iron produced. While the purpose of the gases generated by the partial combustion of carbon is to reduce iron ore, the value of a blast furnace as a gas producer is evident from the relation just noted. The essential reactions by which blast-furnace gas is produced are shown in Chapter 12.

The percentage of CO and CO₂ in blast-furnace gas is directly related to the amount of carbon in the coke and the amount of CO₂ in the limestone charged per ton of iron produced. The rate of carbon consumption depends principally upon the kind of iron to be made, the physical and chemical characteristics of the charged material, the distribution of the material in the furnace stack, the

furnace lines, and the temperature of the hot blast. The total CO + CO₂ content of the top gas is about 40 per cent by volume, and when producing ordinary grades of iron the ratio of CO to CO₂ will vary from 1.7 to 2.5, to 1. The hydrogen content of the gas varies from 3 to 4 per cent. The remaining percentage is made up of nitrogen, except for about 0.2 per cent CH₄. The efficiency of the blast furnace as a gas producer on a cold basis is a little less than 70 per cent; and on a hot basis, about 90 per cent.

Blast-furnace gas leaves the furnace at a temperature of 250° to 700° F, and at a pressure of 15 to 60 inches w.g., carrying with it 10 to 50 grains of water vapor and 8 to 15 grains of dust per cubic foot. The particles of dust vary from 1/4 to 0.00001 inch in diameter. In early days of blast-furnace operation, the gas was used as it came from the furnace without cleaning, causing a great deal of trouble with flues, combustion chambers, and stoves due to clogging. The gas now is cleaned almost universally, the degree depending upon the use.

The outstanding characteristics of blast-furnace gas as a fuel are: (1) very low calorific value—approximately 90 Btu per cu. ft., (2) low theoretical flame temperature—approximately 2650° F, (3) low rate of flame propagation—relatively lower than any other common gaseous fuel, (4) high specific gravity—highest of all common gaseous fuels, and (5) burns with a non-luminous flame.

Coke-Oven Gas—The steel industry, which uses about 85 per cent of the total coke-oven gas generated in the United States, generally classifies coke-oven gas as a by-product of coke manufacture. This undoubtedly is due to the former waste of coke-oven gas and other coal products for so many years in the beehive-coke process. Actually, the production of coke-oven gas and other coal chemicals is a part of an important manufacturing process in which large sums have been expended for their recovery, as they have a value almost equal to that of the coke. Coke-oven gas is produced during the carbonization or destructive distillation of bituminous coal in the absence of air. A description of the carbonization of coal and the recovery of coke-oven gas and coal chemicals is given in Chapters 4 and 5.

The composition of coke-oven gas varies in accordance with grade and density of coal and operating practices. Typical ranges for the constituents of dry coke-oven gas by volume are as follows:

CO ₂ *	1.3 - 2.4
O ₂	0.2 - 0.9
N ₂	2.0 - 9.6
CO	4.5 - 6.9
H ₂	46.5 - 57.9
CH ₄	26.7 - 32.1
Illuminants	3.1 - 4.0
Specific Gravity	0.36-0.44
Heating Value, Btu per cu. ft. (gross) ..	537-580
Heating Value, Btu per cu. ft. (net) ...	480-523

*Includes H₂S

Coke-oven gas contains hydrogen sulphide, H₂S. About 40 per cent of the sulphur in coal, not removed in the washing process, is evolved with the distillation products. Much of this remains in the gas. Carbonization of coals containing 1.20 per cent sulphur evolves a gas containing about 424 grains of sulphur per 100 cu. ft., and those containing 1.60 per cent sulphur about 600 grains per 100 cu. ft. Commercial coals in the eastern part of the United States usually run from 0.5 to 1.5 per cent sulphur. Gases high in sulphur content are very undesirable for metallurgical purposes.

Coke-oven gas normally is saturated with water vapor.

In distribution systems, means must be provided for draining off the condensation due to any temperature change.

Coke-oven gas burns with a non-luminous to semi-luminous flame, depending upon the degree of mixing air and gas. Its rate of flame propagation is high—considerably higher than natural, producer, or blast-furnace gas. It has a low specific gravity—lowest of any of the gaseous fuels commonly utilized by the steel industry. It has a high theoretical flame temperature—about 3600° F, a little higher than that of natural gas. The explosive range is about twice that of natural gas.

Use of Various Gaseous Fuels in the Steel Industry—Gaseous fuels are ideal for many steel-plant applications. Below are the more important applications where gaseous fuels either must be used on account of the nature of the work or facility, or where they are preferred over a liquid or solid fuel:

- Coke-Oven Heating
- Blast-Furnace Stoves
- Gas Engines for Blowing or Power Generation
- Soaking Pits
- Reheating Furnaces
- Forge and Blacksmith Furnaces
- Normalizing and Annealing Furnaces
- Controlled-Cooling Pits
- Foundry Core and Bessemer Bottom Ovens
- Blast Furnace and Steel Ladle Drying
- Drying of Blast-Furnace Runners and
- Open-Hearth Tapping Spouts
- Hot-Top Drying

To these may be added the gas turbine for blowing or power generation when further development permits a more extended use of this machine.

The choice of the most desirable fuel for each of the many facilities in a steel plant is not always possible, but by judicious planning the most efficient fuel or combination can be selected from those available. The general characteristics of each gas govern, wherever possible, its selection for a specific purpose in a steel plant. An outline of the important applications of the major gaseous fuels follows.

Uses for Blast-Furnace Gas—For many years, the use of blast-furnace gas for purposes other than for the firing of stoves and boilers was not economical. A number of factors have contributed, however, to the enlarged use of blast-furnace gas, the more important of which are: (1) rising cost of purchased fuel; (2) technical progress in gas cleaning, in the use of regeneration and recuperation, and in the mixing of gaseous fuels; (3) the economic advantage of using pulverized coal in boiler houses to substitute for blast-furnace gas, thereby permitting its substitution elsewhere for the more expensive liquid and gaseous fuels; and (4) seasonal shortages in the availability of purchased liquid and gaseous fuels.

In certain applications, in addition to preheating the air, the gas itself may be preheated to provide higher temperature potential. For the facilities listed below, blast-furnace gas may be utilized successfully without preheat:

- Blast Furnace Stoves
- Normalizing and Annealing Furnaces
- Foundry Core and Bessemer Bottom Ovens
- Gas Engines for Blowing or Power Generation

The thermal advantage of using blast-furnace gas in blowing engines and gas electric generators must overcome the heavy investment and maintenance expense of this equipment. The modern boiler house utilizing

high steam pressure and temperature with efficient turboblowers and generators has sufficiently reduced the thermal advantage of gas engines so that their use is difficult to justify.

Preheated blast-furnace gas burned with preheated air has been used successfully in the following applications.

Coke-Oven Heating Soaking Pits Reheating Furnaces

When blast-furnace gas is preheated, it should have a minimum cleanliness of 0.01 grains per cu. ft.; and in all cases where this gas is used, extra precautions must be taken to prevent the escape of fuel or unburned gas into attendable surroundings since it contains a large percentage of toxic CO gas. Blast-furnace gas is used for many applications in the steel plant and, in addition, is used frequently for heating coke ovens and sometimes is mixed with other gases as an open-hearth fuel.

Use of Coke-Oven Gas—Coke-oven gas has had a more extended use than blast-furnace gas because of: (1) relatively low distribution costs due to its low specific gravity, high calorific value, and cleanliness; (2) its ability to develop extremely high temperatures by combustion; and (3) the high rate at which it can release heat, thereby eliminating excessively large combustion chambers. Important applications for coke-oven gas include open-hearth furnaces in addition to those previously listed for gaseous fuels. The low specific gravity of coke-oven gas is a disadvantage in the open hearth, and for this reason, it is supplemented wherever possible with a driven liquid fuel in this service. In addition, the sulphur (in the form of H_2S) present in coke-oven gas is a distinct disadvantage, particularly when used in making low-sulphur heats in the open hearth and in heating certain grades of alloy steel for rolling. Its presence also requires the use of materials resistant to sulphur attack in pipe lines, valves, and burners.

There are a number of fuel applications in a steel plant where neither blast-furnace gas nor coke-oven gas, when burned alone, develop the desired flame characteristics or temperature level for optimum results. By mixing two fuels of such great variance in characteristics, a more ideal fuel can be obtained for specific applications.

The speed of combustion is very high for coke-oven gas and very low for blast-furnace gas. The desired speed can be attained through the proper proportioning of the two fuels. The speed also can be modified to a limited extent when necessary by suitable combustion technique. Mixed blast-furnace and coke-oven gas is particularly suitable for application to soaking pits and reheating furnaces.

Use of Natural Gas—Due to plant balances requiring the purchase of outside gaseous fuels, mixtures of coke-oven gas and natural gas are often utilized. While the temperature-developing characteristics of these two gases are nearly identical, they have differences in other characteristics, notably in the rate of flame propagation and in luminosity. By proper proportioning, the advantage of a short, intensive cutting flame or a long, lumi-

nous, soft flame may be had to suit the applications.

Use of Producer Gas—Raw, hot, producer gas has been used extensively in steel-plant operations for open-hearth furnaces, soaking pits, and reheating furnaces. It has been customary to preheat this gas regeneratively when used in open hearths and soaking pits, and also in batch-type reheating furnaces. In continuous-type reheating furnaces, the fuel seldom is preheated. With good gas making, producer gas develops a soft, heavy, long, luminous flame desirable for reheating steel and in working an open-hearth heat. The use of this gas largely has been superseded in many plants by by-product gaseous and liquid fuels.

Combustion of Various Gaseous Fuels—The major combustion reactions of the components of gaseous fuels with air and a table of essential gas combustion constants were given in Section 3 of this chapter. From chemical equations, the quantity of air required to provide perfect combustion and the resultant products may be calculated for any given gaseous fuel. Table 3—XVI shows the air requirements, products of combustion, and pertinent characteristics of several gaseous fuels. The degree of mixing of air with a gaseous fuel, and the degree of excess or deficiency of air to the theoretical requirements are pertinent combustion problems. The degree of mixing is controlled by burner design. Burners have been developed to produce short, intense flames or long, slow-burning flames. The short, intense flame is usually non-luminous or semi-luminous, while the long flame is luminous. This relation is not always the case, however, since a gas must contain hydrocarbons to develop luminosity. Burners capable of producing short, intense flames will liberate a large amount of heat in a small space. Some gases, due primarily to the constituents of which they are composed, are capable of a high rate of heat release; others, of a very low rate of heat release. The two extremes are evident in two common steel-plant fuels—coke-oven gas and blast-furnace gas. There is also a limit to the length of flame which can be produced. It is determined by the ability of the flame to provide enough heat to propagate itself. If the short, intense-flame type burner is used with coke-oven or natural gas, combustion will be so intense that no flame will be visible, and heat can be liberated at rates up to several million Btu per cubic foot of combustion space per hour; while the long, slow-burning-flame burner firing the same gases is capable of developing a visible flame twenty or thirty feet long with a heat liberation of 15,000 to 20,000 Btu per cu. ft. per hour. Both types of flames are desirable for specific steel-plant applications. It is obvious that burner selection based on degree of mixing is important. Carrying an excess or deficiency of air for combustion is practiced usually to control scale formation, but this is done sometimes in order to control flame characteristics. An excess of air tends to shorten, while a deficiency lengthens, a flame. An excess of air above theoretical requirements causes higher heat losses as any extra air absorbs its share of the heat of combustion. When there is a deficiency of air, potential heat is lost. In problems of design and fuel conservation, the air requirements and volume and constituents of the products of combustion must be known.

SECTION 8

FUEL ECONOMY

Since fuel represents the largest single item of expense in assembling raw materials for the manufacture of iron and steel, the subject of fuel economy is of consequence

to both the producer and consumer of steel products. The steel industry consumes annually during normal times about 100 million net tons of fuel in coal equivalent.

^(a)From "Combustion"—American Gas Association.

The efficient utilization of this large quantity of fuel is also pertinent to the conservation of our fuel resources. The history of the steel industry shows great progress has been made in reducing the amount of fuel required to produce a ton of steel. During the Revolutionary War, iron making required large quantities of charcoal, as the source of carbon, to reduce the ore. If a substitute had not been found for charcoal, our forests would have disappeared many years ago and our industrial progress arrested. In the past one hundred years, which really represents the modern era of steelmaking, a number of important developments have taken place to reduce the fuel requirements in producing steel. Some of these developments could be listed by historical sequence, while others are of such a nature that they cannot be designated by any period of time. The major contributions to fuel economy in steel plants have been:

- (1) Development of the Bessemer converter.
- (2) Development of the Siemens-Martin regenerator.
- (3) Development of the hot blast.
- (4) Utilization of blast-furnace gas.
- (5) Installation of by-product coke plants and utilization of by-product fuels.
- (6) Integration of steel plants.
- (7) Electric drives for rolling mills.
- (8) Improved efficiency of steam-generating equipment and steam prime movers.
- (9) Large producing units.
- (10) Balancing of producing units.
- (11) Recovery of waste heat by recuperators, boilers and other forms of heat exchangers.
- (12) Development and utilization of instruments and control equipment.
- (13) Insulation of high-temperature facilities.
- (14) Utilization of the optimum fuel for specific facilities.
- (15) Improvements in manufacturing technique and production control.
- (16) More highly skilled operators.

The results of the above contributions now have made it possible to produce a ton of steel ingots utilizing less than 1½ tons of coal, instead of several tons as required a hundred years ago. The consumption of primary fuels in the iron and steel industry for three recent years is shown in Table 3—XVII.

In addition to these outstanding contributions to fuel economy in steel mills, the importance of the effect that rate of operations has on fuel economy should be stressed. Historically, the iron and steel industry follows the general business level maintained in the country, but its rate of operations often fluctuates more than that of many other industries. During peak production, optimum fuel economy is the natural result of operating the facilities which require fuel under the conditions for which they were designed to operate most economically. During periods of low production, fuel consumption undergoes a severe increase per unit of output; careful scheduling of production and facilities are required during this period to maintain minimum fuel losses.

The effectiveness with which by-product fuels are used in steel plants is of major significance in reducing the quantity of primary or purchased fuel required to produce a ton of steel. The consumption of by-product fuels (blast-furnace gas, coke-oven gas, pitch-tar and coke breeze) for three recent years is shown in Table 3—XVIII.

Of the total gas produced by blast furnaces and coke

ovens, only a portion is available for replacement of purchased liquid or gaseous fuels. Blast furnaces consume 35 to 45 per cent of the top gas produced to operate their own facilities. Fuel is required in stoves to heat the blast, and to provide steam for driving blowers, pumps and electric generators to satisfy furnace demands. By-product coke ovens use the equivalent of 30 to 40 per cent of the gas they produce to heat the ovens in addition to fuel requirements for generating steam for pumping water, process steam and the electric power necessary to produce coke and coal chemicals.

While the primary fuel requirements of recent years represent progress over former years, future utilization of lower grade raw materials (higher ash and sulphur in coal and ore of lower iron content) will require extra diligence and development work to continue the past rate of progress in fuel economy. The present national fuel figure of about 1.3 tons of coal per ton of ingots will be reduced considerably as modern facilities replace those which become obsolete or are of no further economic value, provided the disadvantage of lower grade raw materials is matched by developments in their use. Figure 3—6 illustrates graphically existing potentialities for fuel economy in a steel plant. With modern facilities and efficient practices in a well-balanced and integrated plant, it is possible, as shown in the flow diagram, to produce a ton of ingots with one ton of coal.

Efficiency of Heat Utilization in Steel Plants—1. Blast Furnaces—Blast furnaces require much more fuel than any of the other producing units in a steel plant. However, about half of this fuel is recovered in the form of blast-furnace gas. The efficiency of fuel utilization of the other half required for smelting iron in the blast furnace is very high and no large reduction, such as has been procured during the past twenty years in other processes in the steel plant, can be foreseen. However, any appreciable reduction in blast-furnace coke rates which can be effected will have a beneficial effect upon steel-plant fuel economy as a whole. During the period of World War II, a number of furnaces were increased in size. Practice and tests on some of these revealed potential fuel economies are possible over those of smaller size. Tests with beneficiated ore also have disclosed marked improvement in production and in fuel economy.

The developments of the past twenty years in blast-furnace fuel economy have centered especially on means for procuring better distribution of the gas through the stock and on employment of higher hot-blast temperatures. Better gas flow has been accomplished through improved charging facilities, improvements in the structure and size of coke, in the beneficiation of ore, higher furnace top pressure, and improved furnace lines and working volume. The installation of larger and more adequate stoves has made possible the use of higher hot-blast temperatures.

2. Blast-Furnace Stoves—The fuel efficiency of furnace stoves of older design probably averaged little better than 60 per cent. A comparison of an approximate heat balance of older with modern stoves of 80 to 85 per cent efficiency is as follows:

Item	Former Stoves (%)	Modern Stoves (%)
Heat absorbed by blast.	50 to 70	80 to 85
Sensible and latent heat in stack gases.	20 to 40	10 to 15
Potential heat in stack gases.	2 to 5	0 to 2
Radiation and unaccounted losses.	10 to 25	5 to 10

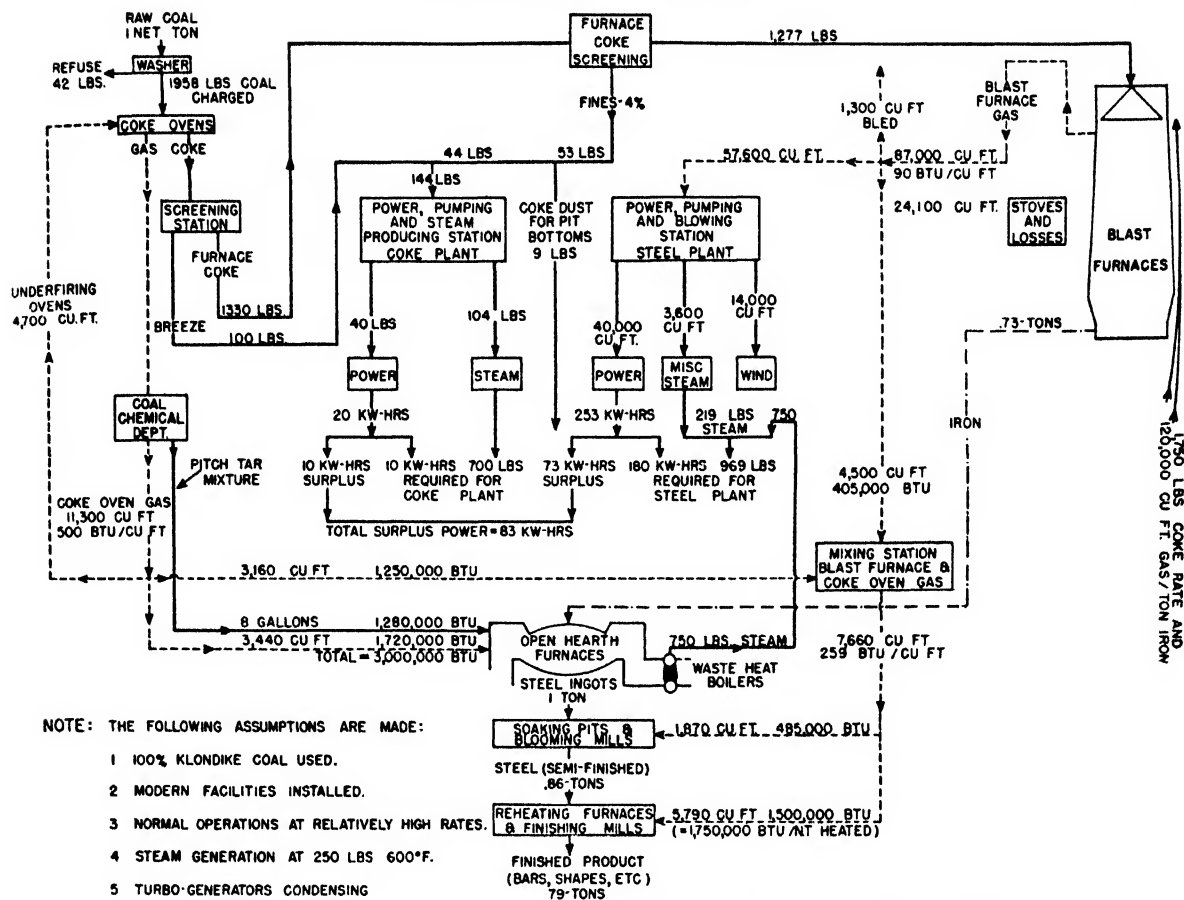

FIG. 3—6. Graphic representation of existing potentialities for fuel economy in a steel plant.

3. Blast-Furnace Blowers—Modern blast furnaces generally are equipped with steam-turbine driven blowers consuming about 18,000,000 to 20,000,000 Btu in steam per blast unit. A "blast unit" is a measure of energy applied to blast-furnace blowing. It is the energy required to compress 1,606,140 cu. ft. of dry air at 60° F and 30 in. Hg adiabatically to 15 lbs. per sq. in. gage pressure, and is equal to 1000 Kwh., or 3,415,000 Btu. Turbo-blowers have replaced many of the older reciprocating-engine-driven compressing tubs or cylinders in which the air was raised to the proper pressure level, an operation which consumed from 30,000,000 to 50,000,000 Btu in steam per blast unit. The gas-engine-driven blowing-tub consumes only about 18,000,000 Btu in gas per blast unit, but its thermal advantage over the turbo-blower is largely overcome by relatively high initial and maintenance costs. Modern turbo-blowers, complete with auxiliaries and efficient boilers (80 to 85 per cent) for producing steam, require about 15 per cent of the total blast-furnace gas produced.

4. Basic Open-Hearth Furnaces—Accomplishments in fuel economy in open-hearth furnaces between 1928 and 1952 outrank those of any other major metallurgical facility in the steel plant, and although available national records are insufficient, it is safe to assume a reduction of 20 to 25 per cent has been made in this interim. In 1926, very few open-hearth shops could boast of consistently producing steel ingots for less than 5,000,000 net Btu per net ton of steel, while today only a few shops require that amount, and the majority of modern shops

seldom exceed 3,500,000 net Btu. The fuel economy effected in basic open-hearth furnaces (largely in the last 20 years) is primarily the result of the development and intelligent use of controls and the gradual change to larger furnaces. Faster charging, reduced bottom delays, minimized hot-metal and pouring delays, better fuels, more effectively designed checkers, ports and burners, and many other factors also have contributed to fuel economy. In addition to the reduction in Btu per ton, large fuel savings, which are not shown by the figures quoted, have been effected by converting the heat in waste gases into steam by the use of waste-heat boilers.

The open hearth, because of the high working temperature required, has very high stack and radiation losses.

The approximate heat balance of a large, modern, open-hearth furnace equipped with waste-heat boilers is shown schematically in Figure 3-7 (see page 85).

Recent technical developments in the use of compressed air or oxygen to hasten bath reactions, atomization of liquid fuels with air rather than steam, enriched air for combustion and better open-hearth refractories, have opened the way for future improvements in the fuel economy of open-hearth furnaces.

5. **Soaking Pits**—Prior to 1930, the majority of soaking pits were of the regenerative type, consuming from 800,000 to 2,500,000 net Btu per ton of ingots, the difference in fuel requirements depending largely upon the temperature of the steel charged into the pits. Several new types which have been developed in recent years, to-

gether with the development and use of automatic controls, have resulted in a reduction of 300,000 to 1,200,000 Btu per net ton of ingots in the fuel consumption for heating ingots.

6. Reheating Furnaces—The fuel consumption of reheating furnaces varies considerably depending upon the temperature of the steel to be reheated, the size and grade of steel, operating schedules and practices, and furnace design. Table 3—XIX shows the fuel consumption generally realized in modern reheating furnaces.

The principal loss which occurs in reheating furnaces is the sensible heat lost in the stack gases. A reduction of this loss has been accomplished by the installation of regenerators, recuperators or waste-heat boilers.

7. Steam and Power Generation—Boilers in steel plants generate steam for driving blowers, electric-power generators, service water pumps, and a multitude of miscellaneous equipment, as well as provide steam for the heating of buildings, shops and offices, and for general process work. About 1928, reciprocating steam engines were the principal source of power in all the older steel plants. Steam lines from several boilers in large plants provided a labyrinth of feeder lines to various furnace and mill facilities. Leakage of steam and condensation losses in lines were high. Steam pressure and temperatures seldom exceeded 150 lbs. per sq. in. gage and 50° F of superheat. Boiler efficiencies usually were in the 50 to 60 per cent range.

A history of the growth of electrification in steel mills is given in Chapter 24, on "Rolling Mill Drives." This growth has had a continued influence since 1906 on national fuel economics. As existing old mill drives and obsolete steam equipment are replaced with modern electrical facilities, further economies will result. Converting steam power to electrical power will in itself use up power, but once the electrical power is obtained, it can be used very efficiently. While a number of modern

boiler houses now installed are 80 to 85 per cent efficient, the national average for steel plants probably does not exceed 70 per cent. The difference offers a major possible unit reduction in future steel-plant fuel requirements.

The efficient utilization of by-product fuels provides a surplus, in well-integrated plants, for the generation of electric power. A modern fully-integrated plant is capable of generating all of its own power requirements from available surplus by-product fuel. Table 3—XX shows the electrical energy consumed annually by the steel industry in 1950, 1951, and 1952. It also shows the amount of electrical energy purchased from public utilities and that generated within the industry. At least 30 per cent of the electric power requirements in these years was generated by the steel industry itself.

Table 3—XX. Consumption of Electrical Energy in Steel Industry (In Millions of Kwh.)^(a)

Year	Generated	Purchased	Consumed
1952	8,686	17,259	25,945
1951	9,241	18,370	27,611
1950	8,976	15,688	24,664

^(a)"Annual Statistical Reports," American Iron & Steel Institute.

Many of the existing turbines used for blowers, generators, service water pumps, and other facilities installed prior to 1930 were designed for steam pressures under 250 lbs. and 550° F temperature. Future replacement of these facilities will provide further fuel economies, as estimated in Table 3—XXI.

Means Employed for Heat Conservation—The heat from the combustion of fuel which is not utilized in steel-plant metallurgical and service facilities represents an appreciable part of the total supplied. The amount lost differs with various processes. In general, the processes having the higher temperature levels have the greater thermal losses, and, therefore, offer the best opportunity for heat recovery. The largest losses usually are contained in the waste flue gases and in radiation from the furnace walls. The recovery of heat from waste flue gases of high-temperature processes has been practiced for nearly a hundred years. Since that time, improvements in design of the originally conceived regenerators, and the development and use of recuperators and waste-heat boilers, have made possible substantial recovery of heat losses. The reduction of radiation losses by the use of insulating material has been practiced in some processes for possibly fifty years; in others for relatively only a few years. The utilization of higher steam pressures and temperatures and more efficient facilities for steam generation has progressed slowly but definitely in the past two decades.

Waste flue gases contain both sensible heat and the

latent heat of vaporization of water and sometimes potential heat (unburned fuel gases). The recovery of the heat of vaporization of water is not practicable, and the elimination of potential heat in waste flue gas is controlled by providing sufficient air for combustion at the burners. The amount of sensible heat in waste flue gases is the product of the heat content per cubic foot or pound of gas, times the volume or weight of gases.

The total loss of heat in waste flue gases is minimized by providing only sufficient air for combustion, and by preventing air infiltration. The temperature of furnace exit gases is lowered by observance of heat-transfer principles. Waste flue-gas temperature is reduced and heat recovered by heat exchangers such as regenerators, recuperators and waste-heat boilers. The heat content of the products of combustion of coke-oven gas and natural gas at different temperatures for various amounts of excess air is shown respectively in Figures 3-8 and 3-9.

Fuel-Air Proportioning—In modern steel-plant furnaces, and in boilers, the amount of air supplied for combustion is maintained only a little above theoretical requirements by automatically controlling its flow in chosen proportion to the supply of fuel. In open-hearth and some other regenerative furnaces in earlier times, air for combustion was drawn into and through the regenerators solely by the draft created by the furnace stack. Crude attempts were made to control the supply of air by opening or closing the stack dampers. Where

preheated gas was used as fuel, the problem was still more complicated.

In modern furnaces of this type, all possible points of leakage in the furnace system have been sealed to prevent air infiltration, and controlled quantities of air, in selected proportion to the amount of fuel supplied, are blown into and through the regenerators and thence into the furnace to mix with the fuel to provide the controlled combustion. In other types of furnaces, such as in heat-treating furnaces, special pressure regulators and valves accurately proportion the amounts of fuel and air fed to the burners and effect the same result.

Accurate and automatic proportioning of fuel and air has contributed to improvements in fuel economy, furnace efficiency and process control in the relatively recent past. The control of the rate of firing has also made important contributions and will be covered under "Automatic Temperature Control."

Oxygen Enrichment of Combustion Air—Air is composed of only about 20.9 per cent oxygen, with the remainder consisting of inert nitrogen plus a small amount of several other inert gases. When combustion takes place, the oxygen combines with the carbon and hydrogen to the fuel and liberates heat. The inert gases of the air absorb heat from the combustion and carry it out of the furnace, and it is lost so far as the furnace process is concerned. They reduce flame temperature by absorbing heat, thus reducing rate of heat transfer to the work.

It has been known for a long time that if the inert

FIG. 3-8. Heat content of products of combustion of coke-oven gas at different temperatures for various amounts of excess air.

FIG. 3-9. Heat content of products of combustion of natural gas at different temperatures for various amounts of excess air.

content of air could be diminished, much more efficient combustion could be attained. Recent technical developments that have lowered the production cost of oxygen of commercial purity have made large-scale use of this gas economical for some industrial processes. Consequently, many plants have experimented with the addition of oxygen to ordinary air used for combustion, with generally good results. In effect, increasing the oxygen content lowers the inert content of the air; consequently when a given amount of fuel is burned with oxygen-enriched air, the volume of waste gas is less than if ordinary air is used. If the temperature of the waste gas is not increased, the sensible heat loss in the flue gas will be decreased, due to the smaller heat capacity of the smaller volume. In furnaces operated at a high thermal head, a diminution of the inerts usually results in a decrease in waste-gas temperature. With the same fuel input, enriched air for combustion raises flame temperature of a given fuel, thereby improving heat-transfer rate and increasing production; alternatively, the fuel input may be decreased when enriched air is used, to maintain the same production rate as obtained with more fuel using ordinary air. Increased production rates almost always reduce the heat losses per ton of product in any furnace employing a high thermal head.

Furnace Pressure Control—If the pressure of the gases in the heating chamber of a furnace is below atmospheric, cold outside air will be drawn into the furnace through any openings that exist. If the interior pressure is above that of the outside air, the hot gases will be forced out of the furnace through these same openings, and if too much higher will, in addition, tend to penetrate the refractories with, in some cases, damaging effect. It is desirable generally to operate a furnace with a slight positive pressure in the heating chamber (i.e., furnace pressure slightly higher than atmospheric). It should be noted that the pressure from top to bottom of the heating chamber is not uniform, due to the stack effect of the hot gases. Control, therefore, is aimed at maintaining the desired pressure at hearth level.

Air drawn into a furnace operating under negative pressure upsets the fuel-air ratio which is controlled automatically or by valve settings. In some furnaces, such as reheating or heat treating, this air aggravates the problem of oxidation (or scaling) of the work because of the oxygen present.

If the pressure in the furnace at hearth level is equal to atmospheric or slightly positive, better heating conditions are obtained by improving heat transfer, and by better control of temperature uniformity. This is especially so in furnaces where most of the heating of the work takes place through heat transfer by radiation from the flame to the bath or work. The positive pressure must be controlled to prevent excessive sting-out of flame from furnace openings (a small pressure imparts a high velocity to hot gases), as well as to avoid the build-up of excessive back pressure that would interfere with the proper flow of fuel (if gaseous) and combustion air. Positive pressures maintained at hearth level in practical work are quite low, ranging only up to a few hundredths of an inch of water. Furnace pressure is controlled by adjusting the opening in the stack damper.

Positioning of the damper can be done manually, using the flame sting-out as an indication of the existence of a positive pressure, but it is difficult to adjust the opening for the frequent changes in furnace conditions. The development, about the year 1928, of industrial-type instruments with sufficient sensitivity to measure differential gas pressures with an accuracy of ± 0.0025 inch

of water, made possible the use of automatic control of furnace pressure. Such instruments employ a diaphragm (or equivalent) to measure the difference between furnace and atmospheric pressure, and, through electrical relays or other devices that operate motors or by hydraulic systems, move the stack damper automatically to maintain the desired pressure in the furnace.

Automatic furnace-pressure control has been provided for the majority of steel-plant furnaces, and has been a principal factor in the improvements in fuel economy and efficiency of melting and reheating furnaces in the steel industry during the years following its adoption.

Automatic Temperature Control—By eliminating as nearly as possible human error in judging temperatures by senses, automatic instruments for measuring temperature have contributed largely to the improvement and economy of many steel-plant operations. The use of excessive amounts of fuel is wasteful of the fuel itself and results in high furnace exit gas temperatures and damage to refractories. In some processes, high fuel rates not only do not hasten transfer of heat to the material being processed, but also may cause actual damage to it. The use of insufficient fuel reduces the rate of heat transfer and prolongs process time, thereby increasing thermal losses. The optimum fuel rate for protection either of the material being heated or the furnace refractories, and often for control of heating or production rate, is maintained in many types of furnaces by automatic temperature-measuring instruments which control the fuel rate by actuating electrical relays or other units which control the operation of motors, hydraulic systems, or other means for regulating valves which control the fuel rate. It would be impossible within the scope of these pages to discuss even briefly the many types of instruments and auxiliaries used for the automatic control of temperature; however, it may be stated that the instruments employed for measuring high temperatures in the steel industry operate on three main principles: (1) by measuring the intensity of radiation emitted by the hot furnace or object; (2) by measuring the minute electric current generated in a circuit composed of two wires of dissimilar metals, joined end to end, when one of the joints is heated (this is the principle of the thermocouple), and (3) by measuring the change in electrical resistance of conductors when heated to the temperature in question.

Regenerators and Recuperators—Regenerators are used alternately to absorb heat from one fluid and then transfer it to another fluid; recuperators are used to transfer heat continuously from one fluid to another. The fluids referred to in these two definitions are: (1) hot, gaseous products of combustion which give up heat during passage through the regenerator or recuperator and (2) fuel gas or air for combustion which undergo heating while passing through the regenerator or recuperator. Regenerators are applied usually to furnaces which can be fired alternately from the ends, the flow of gases through the furnace and regenerators being reversed by predetermined time and/or temperature cycles. Open-hearth furnaces, and many soaking-pit and batch-type reheating furnaces, are equipped with regenerators. Blast-furnace stoves also use the regenerative principle but operate over a much longer cycle and in a somewhat different manner than that practiced in other installations. In a blast-furnace stove, the checker brick is heated by burning a fuel exclusively for the purpose of heating the regenerator brick while in the open-hearth and other furnace installations the checkers are heated by waste gases. In both cases, the heat stored in the regenerators is used to preheat air for the combustion of fuel in the furnace they serve.

Recuperators have been applied in many cases to modern pit-, batch- and continuous-type reheating furnaces, and to steam boilers. When applied to steam boilers, they are commonly called "air preheaters." Recuperators are of three general types, classified according to the direction of flow of the waste gases and air, as follows:

1. Counter-flow
2. Parallel or co-current flow
3. Cross flow

Counter-flow is used to attain maximum air-preheat temperatures; cross-current flow to secure optimum heat-transfer rates (Btu per sq. ft. of recuperator surface per degree F temperature difference per hour). Parallel flow is used where it is desirable, such as in metallic recuperators, to maintain the temperature of the division wall between the two fluids as uniform as possible throughout its length and to hold the temperature of the hot end to a minimum. Generally, a combination of the first and third types is applied to many steel-mill furnace applications where a refractory material is used to divide the two fluids. A combination of the two types is accomplished by baffling the flow of one of the fluids. In such designs, the general direction of flow of fluids exchanging heat is countercurrent and the flow in each baffled section is cross-current. Where the temperature of the waste-gas from which heat is to be extracted is relatively low, say under 1800° F, metallic tubes are generally used since they possess an advantage against leakage. High-temperature recuperators are generally constructed of a clay or silicon-carbide material.

Waste-Heat Boilers—These units are used to obtain heat recovery when the practical limit of recovery has been obtained by regenerators or recuperators and there is still sufficient heat left in the waste gases to justify expenditures for waste-heat boilers. In modern large, stationary open hearths, waste gases leave the regenerators at temperatures of approximately 1200° F, and from this level waste-heat boilers recover 30 to 33 per cent of the fuel used, converted into steam. Waste-heat boilers also are used sometimes in place of regenerators or recuperators, depending on conditions such as where preheated air is undesirable or where the generation of steam solves the problem of fuel conservation more satisfactorily.

Waste-heat boilers are most applicable to high-temperature, continuous processes and have been used principally in the steel plant in connection with open hearths and, to a lesser degree, with reheating furnaces and soaking pits. Fire-tube and water-tube boiler types have been installed, the former being the preferred type, generally of horizontal, single-pass design. Approximately 35 sq. ft. of boiler heating surface per ton of stationary open-hearth capacity, designed for high mass velocity of waste gases through the tubes to develop a scouring action for keeping the tubes clean and to provide high heat transfer, is used normally. Waste-heat boilers usually are provided with superheaters and sometimes with economizers.

Insulation—Thermal insulating materials have been used in steel plants for a great many years. There are many different kinds of insulating materials, each being most suitable for a specific temperature level and for the degree of insulation desired. Early applications were made to enable a facility to function more satisfactorily. Insulating material, such as Kieselguhr, was used to line the shell of a blast-furnace stove to aid in the retention of heat for later use by the blast furnace. Steam lines were covered with asbestos or other material to

prevent condensation of steam and consequent loss of power or trouble with blowing or mill engines. The value of insulating material to conserve fuel, to afford safer and more comfortable working conditions, to protect materials susceptible to damage from heat and thermal strain, and to speed up furnace operations became evident and the progressive application of insulating material to practically all facilities which employ heat has proven beneficial to steel-plant economy. The high thermal heads at which many steel-plant operations are carried out are particularly conducive to the use of insulation for preventing large losses from radiation. In the modern steel plant, the use of insulation is justified in terms of fuel saved in boilers; stoves; open-hearth regenerators; reheating, pit, forge and annealing furnaces; steam, hot-blast and preheated-air lines; and many other miscellaneous facilities. In some operations, such as in the open hearth, the use of insulation is restricted by the temperature the refractories will stand; consequently, radiation losses are still very high. Heat losses have been reduced in such cases by sealing cracks and openings in a furnace wall to prevent heat loss from radiation, exfiltration of gases and infiltration of cold air. Further progress in the development of high-temperature refractories will permit further insulation. The development of insulating firebrick in recent years is particularly significant to the fuel economy of furnaces which are operated intermittently. Many of the older furnaces are constructed of heavy refractory walls which must be heated up before the furnace is capable of producing at normal rates. These heavy furnace walls soak up considerable heat, which must be supplied by fuel. The replacement of these furnace walls with much lighter insulating firebrick permits heating up more rapidly because of less heat absorption, and permits increased production.

Instruments, for measuring temperature, pressure, volume, weight, electrical energy, etc., are used extensively in the steel industry as operating guides. They benefit fuel economy directly or indirectly.

Chapter 4

METALLURGICAL COKE PRODUCTION

SECTION 1

INTRODUCTORY

Selection and Preparation of Coal for Coking—Coke is the term used to describe the residue from the destructive distillation of bituminous coal. Structurally it is a cellular, porous compound which also is heterogeneous in both physical and chemical properties. The physical properties of metallurgical coke, as well as its composition, depend largely upon the coal used and the temperature at which it is carbonized. Not all bituminous coals will form coke, and not all coking coals will give the same firm, cellular mass characteristic of coke suitable for metallurgical purposes. Some coals will produce an acceptable coke without blending with other coals, while others are usable only as constituents of blends. Chapter 3 already has described how preparation of coals prior to coking is an important element in metallurgical-coke production. The type and method of operation of coking facilities also exert a profound influence on the quality and yield of coke for the blast furnaces.

Kinds of Coke—There are three principal kinds of coke, classified according to the methods by which they are manufactured: low-, medium- and high-temperature coke. All of the coke used for metallurgical purposes must be processed in the higher ranges of temperature if the product is to have satisfactory physical properties. Even with good coking coal, the product obtained by low-temperature carbonization (900° to 1400° F) is unacceptable for metallurgical purposes.

It is generally agreed that the most desirable blast-furnace coke is made from mixtures of high-volatile and low-volatile coals, pulverized and blended and then coked in ovens capable of heating the mass to a uniformly high temperature.

At the majority of coke plants, high-volatile coking coals are blended with low-volatile coals in varying percentages, depending on the particular coals, the purpose being to produce coke of high quality and yield. In the earlier days of the coke industry, some of the coking coals used were superior to those currently being carbonized. Some progress has been made in the utilization of coals which expand and exert pressures on oven walls during coking. In addition, it is generally conceded that higher ash and sulphur coals are acceptable currently for coking purposes than in use in former years. In all probability the practice of blending coals has been one of the greatest single factors in the extension of coal reserves usable for coking purposes. At present, laboratory scale tests are available which are capable of evaluating both the coking and expansion characteristics of individual coals or blends. A few plants retain the practice of using only a single coal for coking purposes while others use mixtures of high-, medium- and low-volatile coals for coke production.

The practices followed in this respect are determined largely by economic considerations.

The acceptability of a coal for metallurgical coke production depends on various factors relating to its chemical and physical characteristics as well as its economic availability. While laboratory tests can be used to develop data to permit evaluations in this respect, final appraisal can be determined best by actual full-scale plant test under exact conditions of their use.

Factors Controlling Properties of Metallurgical Coke—Coke for blast-furnace consumption must be sufficiently firm and strong to resist shattering by handling, and crushing by the pressure exerted by the heavy blast-furnace burden. It should be free of dust and fines, and in pieces not too large for optimum speed of combustion. With a good coking coal, these physical properties can be controlled only moderately by the coking process. As the coal is heated, it becomes plastic at 660° to 890° F, forming a fused mass irrespective of its form when charged into the retort, and through this range of temperature, volatile matter is given off, rapidly at first, then more slowly up to about 1740° F. The coals making up a blend, so far as possible, should have about the same plastic range. Slow heating through the plastic range increases slightly the hardness of the coke. The size of the lumps of coke depends largely upon the thickness of the coal charge and whether or not it is heated from one or both sides. As to chemical composition, a good metallurgical coke will contain very little volatile matter—not over 2 per cent—and 85 to 90 per cent fixed carbon. The remainder is ash, sulphur and phosphorus. The phosphorus content, 0.018 to 0.040 per cent for making Bessemer iron, preferably should be low also for basic iron. Sulphur varies from 0.6 per cent to 1.5 per cent, but is desired as low as possible because coke is the chief source of sulphur in the pig iron produced. Standard specifications for foundry coke call for a volatile-matter content of 2 per cent, a maximum sulphur of 1 per cent, a maximum moisture of 3 per cent, and a minimum fixed carbon of 86 per cent. Shatter and tumbler tests are also specified, but no standard for combustibility has been adopted. These requirements are controlled through selection of the coal, which should be low in sulphur, free from slate or removable refuse, and give an ash which has a moderately-high fusion point in a reducing atmosphere. The question of why coals coke is not fully understood.

Methods of Manufacturing Metallurgical Coke—There are two methods for manufacturing metallurgical coke, known as the beehive, and the by-product or retort process. In the beehive process, air is admitted to the coking chamber in controlled amounts for the purpose of burning therein the volatile products of the coal to

generate heat for further distillation. In the by-product method, air is excluded from the coking chambers, and the necessary heat for distillation is supplied from external combustion of some of the gas recovered from the coking process. With modern by-product ovens, properly operated, all the volatile products liberated during coking are recovered as gas and coal chemicals, and about 40 per cent of the gas produced is returned to the ovens for heating purposes. While the beehive process was the leading method for the manufacture of coke up to 1918, it now has been replaced largely by the by-product process. There are still places, however,

where beehive ovens serve a useful purpose. This is due to the fact that the beehive oven is more flexible in operation and capable of peak coke production more economically than the by-product type oven. As far as can be determined, the processes of manufacture have little effect on the quality of the coke for blast-furnace use. There is a difference in coking temperature of the two processes, that of the by-product being somewhat lower than the beehive. Beehive coke is usually larger, though not as uniform in size. In general, properly carbonized beehive and by-product coke are silvery gray in appearance when quenched with fresh water.

SECTION 2

THE BEEHIVE PROCESS FOR CARBONIZING COAL

Construction of Ovens—As shown in Figure 4—1, the name beehive is literally descriptive of the form and construction of the beehive coke oven. Beehive coke oven plants constructed in the past have followed three general arrangements, as follows: (1) the bank system, in which the ovens are built in single rows against a bank of earth, natural or artificial, thus making it necessary to build but one retaining wall along the front of the ovens; (2) the single-block system, which consists

of a single row of ovens with retaining walls at both the front and back; and (3) the double-block system, in which the ovens, in a double row, are built back to back or staggered with a retaining wall extending along the front of each row. Figure 4—2 illustrates the double-block system.

Waste-Heat System—Early in this century, an occasional beehive coke-oven battery, usually of the banked ovens, was arranged for utilizing the waste heat

FIG. 4—1. Ideal section of beehive coke oven in a single-block battery, showing refractory brick lining, the clay and earth fill, the arched door through which the coke is watered and drawn, and the trunnel head at the top through which the coal is charged and the volatile products escape. Vertical lines in the coke bed indicate the fissures that develop during coking, giving beehive coke its characteristic columnar structure.

FIG. 4-2. Schematic diagram showing arrangement of beehive ovens built according to the double-block system.

from the products of combustion to generate steam. A large tunnel was constructed in the bank some 10 feet back of the ovens and parallel to the battery. This tunnel was connected to each oven by a flue which conducted the hot gases out of the oven from an opening sufficiently above the side wall to prevent its being closed by the largest charge of coal. Each flue was provided with a damper for closing off the draft during the period when the oven was being watered, drawn, and charged. From the battery, the tunnel passed to the boiler house, where branches conducted the hot gases through the fireboxes and flues of the boilers to a common stack. The stacks used were about 100 feet in height to produce proper draft. During the coking period, the coal-charging hole on the ovens necessarily was kept tightly closed. Owing to the increased draft, these ovens were inclined to run at a little higher temperature than ordinary beehive ovens, causing the temperature in the tunnel to be high, sometimes reaching 2730° F. A maximum of about 20 horsepower per oven was generated from the waste heat from a battery. This method did not achieve widespread popularity in this country and was used only at a few plants.

Charging—The ovens are charged as soon as practicable after drawing, in order that stored-up heat from the previous charge will be sufficient to start the coking process. New ovens must be heated up gradually to the coking temperature by wood and coal fires, after which small charges of coal for coking are used until the ovens reach normal working conditions. With the oven in

readiness for charging, the door is partially bricked up and the charge is dropped through the trunnel head from the larry car above, leaving the coal in a cone-shaped pile in the oven. In order to secure uniform coking of the coal, this pile must be leveled so that the coal will lie in a bed of uniform depth over the entire bottom of the oven. This leveling may be done by machine or by hand. In works not equipped with a machine, the leveling is accomplished by a large long-handled scraper, operated through the door of the oven, which is purposely bricked up to only two-thirds of its height at the time of charging. After leveling the coal, the door opening is then bricked up to within about 1½ inches of the top.

Coking Process—The coking process begins very soon after leveling is completed, as the ovens retain enough heat in the brick of the walls and the loam backing to start liberation of the volatile matter from the coal. As more heat is absorbed by the coal charge, the temperature of the oven soon reaches the "kindling" (ignition) point of volatile gases, which, in the presence of the air admitted to the oven, ignite with a slight explosion at first, and then continue to burn quietly in the crown of the ovens, or as small candlelike flames at the surface of the coking mass, thus supplying heat to continue the process. Coking proceeds from the top of the coal downward, so that the coking time depends mainly upon the depth of the coal. The generation of gas thus rapidly approaches a maximum, which is maintained for a period, then declines to practically nothing. The

burning of volatile matter during this period must be regulated by gradually closing up the opening at the top of the door for admission of air. This regulation is necessary to maintain the temperature at a maximum, and conserve coke, as an excess of air at the beginning of the coking period tends to cool the oven, and later consumes the carbon of the coke. The yield is also reduced by improper leveling. If the coal is not of uniform depth in the oven, the thin portions coke through before the thick, and some of the coke of the thin sections is consumed while the coking of the thick portions is being completed. On the other hand, if the process is stopped when the thin areas have coked through, there will be a loss due to uncoked butts on the thick areas. In the coking of bituminous coals in beehive ovens, coking proceeds downward from the top of the charge in which the coal, at increasing depths, passes through a plastic state as the temperature rises. This produces expansion and contraction of the charge with the result that the cake is ramified by a great number of irregular vertical fissures, thus giving it a long columnar structure. These very irregular columns extend from the top to the bottom of the cake. This structure affords a means by which beehive coke can be distinguished from by-product coke.

Watering and Drawing—At the end of the coking time, the brickwork closing the door is torn out, and the coke is watered out. Usually, this watering is accomplished by a self-propelled spraying device. It consists of a tube or pipe a few inches shorter than the diameter of the oven, pivoted at the center to a feed pipe and perforated by two rows of holes on opposite sides, starting from the center. The holes are arranged to throw jets of water horizontally, which causes the pipe to revolve. Where this device is not provided, the ovens are watered by spraying with a stream of water

through the door of the oven. After watering, the coke may be drawn either by hand or machine. As the work is arduous, a machine known as the Covington coke-drawing machine is commonly employed. It is provided with a long arm fitted with a head, flat on the bottom, but inclined on the top, and a pair of hinged ears, or drawing lugs. Upon being pushed by motor into the oven, the head moves in advance of the drawing lugs, which lie flat, and raises the coke from the bottom of the oven. Upon the return, the lugs engage this loosened coke and force it through the door in advance of the head to fall upon a conveyor system that carries it to a screen, from which it passes to railroad cars. It is impossible to remove all the coke with the machine, and what remains must be drawn out by hand upon the conveyor. In straight hand-drawing, the coke is drawn out into the yard and forked into barrows, which are used to wheel the coke into railroad cars. The forking and screening leave the coke free of smaller particles called breeze.

Present Status of Beehive Process—The beehive process still holds an advantage for certain peak requirements where the high investment cost of a by-product plant cannot be justified because of long inoperative periods. Beehive coke is usually made near the mine that supplies the coal, which in turn is determined largely by the availability of coal which can be coked successfully in this type oven.

Due to adaptability the coals used formerly were seldom pre-treated or blended with other coals. Because of depletion of coals in these areas and due to the rather limited range of individual coals that are suitable for beehive-coke making, it is possible that this method will find decreasing future use unless blended coals can be used economically or some process developed for recovery of waste gases.

SECTION 3

THE BY-PRODUCT PROCESS FOR CARBONIZING COAL

The by-product process, being a true distillation process, involves the use of retort ovens. While there are many modifications, these ovens consist essentially of three main parts; namely, the coking chambers, the heating chambers, and the regenerative chambers—all constructed of refractory brick. The coking chambers are rectangular in section, varying in general from 30 to 42.6 feet in length, from 6 to 14 feet in height, and 12 to 22 inches in width. From 10 to 100 ovens constitute a battery of ovens, in which coking chambers alternate with heating chambers so that, in effect, there is a heating chamber on each side of each coking chamber. The regenerative chambers are underneath the heating and coking chambers. Separating walls, between regenerators, also serve as foundation walls for the heating and coking chambers. The entire structure is supported either from the ground or by columns under a structural-steel base. The coal is charged through openings in the top of the oven, and the coke is pushed out from one end by a power-driven ram, or pusher, acting through the other end. All quenching or watering of hot coke is done outside of the oven. During the coking period, the ends of the oven are closed by refractory-lined doors, which must be constructed so as to effect complete sealing of the oven. The ovens first constructed in the industry provided a space between the door and the jamb which was filled with a special luting mixture prior to charging. Later several types of self-sealing

doors were developed, which seal the opening when put in place and require no luting. To permit the escape of the volatile matter, which must undergo several different treatments to separate the various coal chemicals, an opening is provided through the top and at one or both ends of the oven. This opening is fitted with an offtake pipe, which in turn connects with the gas-collecting main for the battery.

The combustion chambers consist of a great number of flues in order to promote uniformity of heating throughout the entire length of the oven. Ovens with both horizontal and vertical heating flues have been built but the latter has largely replaced the former in present installations. While some of the older ovens employed the recuperative principle for preheating the air for combustion, modern practice demands the use of regenerative chambers, because the heat is better conserved and less gas is thereby required to heat the ovens. In the arrangement of these regenerators, two plans have been employed. By the first plan, the regenerative chambers, two in number, are placed longitudinally beneath a whole battery of ovens; with this arrangement, the ovens of a battery are at right angles to the regenerators. Each end of each oven is connected to one of the regenerators. The flow of gases, obviously, must be reversed simultaneously for all ovens in a battery when changing from one regenerator to the other. This precluded, to a great extent, precise heat regulation for an individual or selected

group of ovens in a battery. This type oven did not achieve widespread popularity in this country. In the second plan, individual regenerators are placed under each oven. This plan permits control of the preheated-air supply for combustion to individual vertical heating flues, and makes closer control of heating possible to improve uniformity of heat distribution, in conjunction with other refinements made practicable by this system. Another advantage of using individual regenerators is that each oven is thus made more nearly an independent unit, and the operation of the whole battery is not liable to be influenced by one or two ovens that may be shut down for repair or other reasons.

Heating of individual ovens is controlled so that the temperature at the base of the flues in which gas is being burned does not exceed 2600° to 2700° F, which is considered the safe maximum temperature range to which coke-oven refractories should be subjected. With the flues operating within this temperature range, coking time depends upon the width of the oven, the nature of the coals being coked, and other factors. In general, a coking time is selected that will produce a uniform "skin temperature" of the block of coke in the oven of from 1900° to 2000° F at the time the charge has been coked all the way through to the center. The "skin temperature" referred to above applies to the coke adjacent to the walls of the oven. The time required for coking coal under the above operating conditions will vary from 16 to 20 hours, depending upon the factors already stated. Average time is about 17 to 18 hours.

Modern Types of By-Product Ovens in the United States—In the steel industry in the United States, the transition from beehive to by-product ovens was accelerated with the start of World War I when the construction of by-product coke ovens was started in many

locations in the eastern and central states. While some of the ovens erected at that time are still in operation, a large number either have been rebuilt "in kind" or replaced with ovens of different design. The present popular designs in the United States, largely named after either the designer or builder, are the Koppers, Koppers-Becker, Wilputte and Semet-Solvay. The chief differences in design of these four types involve the heating systems employed. Figure 4-3 illustrates schematically, by simplified sketches, how each type is heated. More detail is given in the text and in subsequent illustrations. Ovens of these four designs comprise about 97 per cent of the by-product coking capacity in this country.

Metallurgical coke, while still the primary product, no longer commands the almost exclusive consideration in oven design as in former years since the coal chemicals recoverable in the by-product process are in constantly increasing demand.

The Koppers Oven—This type of by-product oven, more technically referred to as a regenerative, single-divided oven, was the most prominent around 1916 and many are still in operation. In a typical oven of this period (Figures 4-3, 4-4, 4-5 and 4-6), all parts except the foundation and battery top are constructed almost entirely of the best grade of silica brick.

The majority of this type oven initially constructed in the United States had a coking volume of 500 cubic feet. The dimensions of these ovens were: length, 37 feet from face to face of the doors; height, 9 feet, 10 inches from floor to roof; and width, tapering from 17 inches at the pusher end to $19\frac{1}{2}$ inches at the discharge end. Usually four charging holes were provided in the top for admitting the coal charge, while a separate opening at one end provided an outlet for volatile matter. The

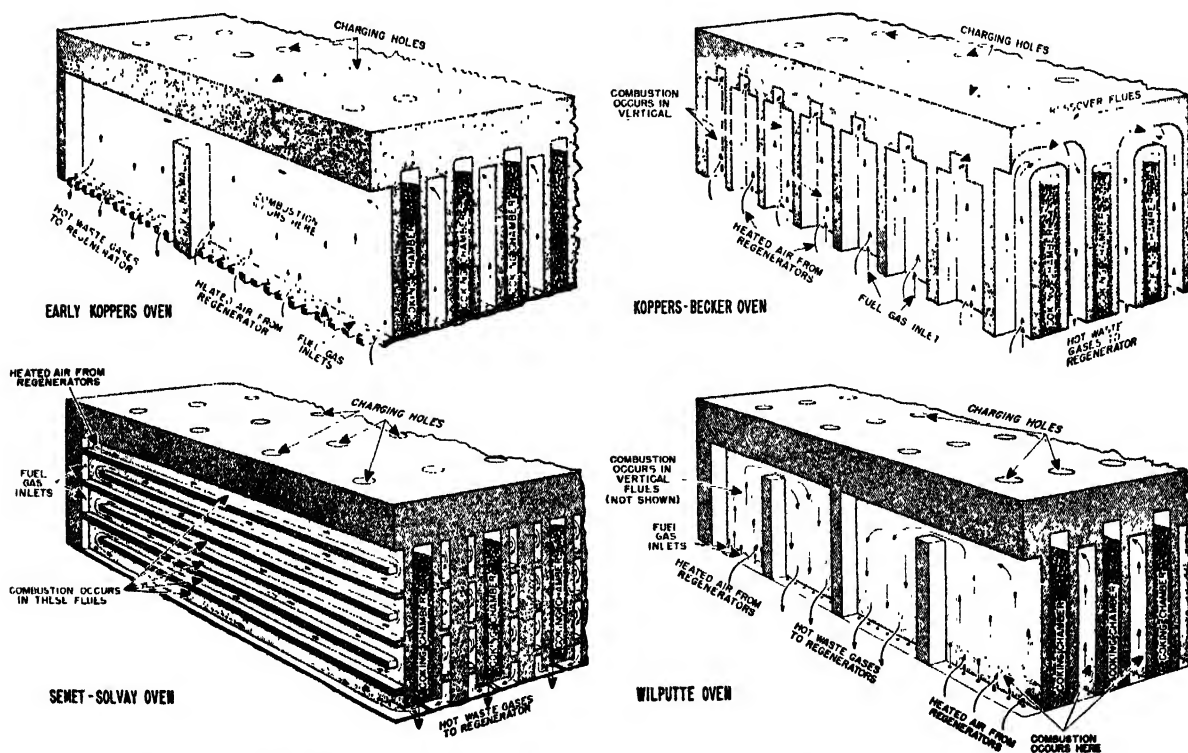

FIG. 4-3. Schematic representation of the differences in firing methods employed in the four most common types of coke ovens. Individual flues are not shown, except for the Semet-Solvay oven. The firing procedures shown are for a single phase of heating which is reversed at the end of a specified period.

FIG. 4-4. (Above) Schematic section through coking chamber and regenerators and (below) section through combustion chambers, showing the paths of air, fuel gas and products of combustion in a Koppers 500-cubic foot coke oven. (See also Figures 4-3, 4-5 and 4-6).

oven is of the vertical-flue type with individual regenerative chambers (Figure 4-6). The heating chamber has a total of thirty vertical flues (Figure 4-5). They are provided with openings to the regenerative chambers, the fuel gas mains, and to a large horizontal flue on a level a little below the top of the coking chamber. A dividing wall near the middle of the oven separates

the heating chamber, except the horizontal flue, into two parts with sixteen vertical flues on the narrower end of the oven and fourteen on the wider end. Each end, approximating half of the oven, may thus be heated alternately, and in practice the reversals are made automatically every half hour for each battery of ovens by a reversing mechanism controlled by an automatic timing

THE MAKING, SHAPING AND TREATING OF STEEL

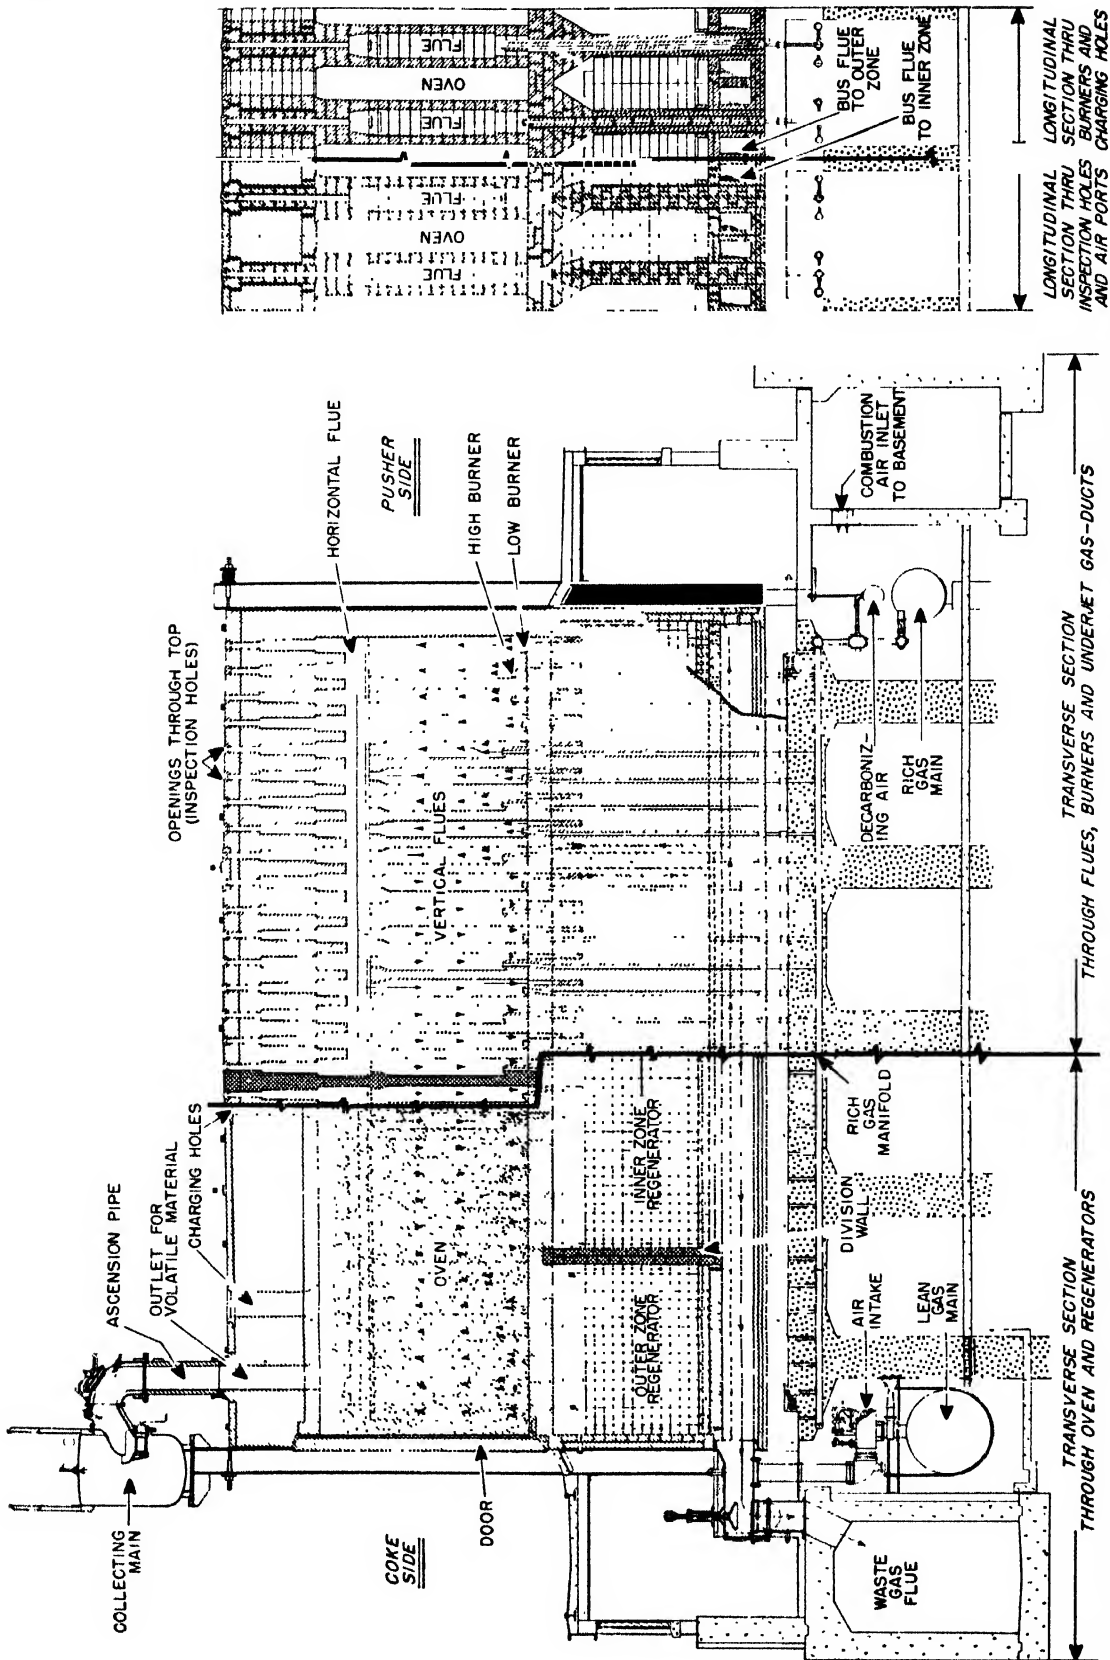

FIG. 4-9. Sections through a battery of Wilputte underjet, combination, by-product ovens, designated as "double-divided" ovens, having two outer zones and one double inner zone in the heating system. The rich gas and lean gas referred to on the drawing are coke-oven gas and blast-furnace gas, respectively. See also Figures 4-3 and 4-14 (Courtesy, Wilputte Coke Oven Division, Allied Chemical and Dye Corp.).

FIG. 4-10. Schematic sections showing paths of air, fuel gas and products of combustion in a Semet-Solvay coke oven. Upon reversal, the direction of the arrows in the upper drawing that indicate direction of flow of air and waste gas are reversed.

device. Two large underground flues, one on each side, extending along both sides in front of, and parallel to, the battery and connected to the checker chambers by

cast-iron air boxes, provide for escape of the products of combustion. These flues lead to a stack about 200 feet high at one end of each battery to furnish the draft necessary to draw the gases through the heating system. An idea of the magnitude of the structure may be gained from the fact that a single battery of sixty-four ovens contains the equivalent of about 2,500,000 nine-inch brick.

The Koppers-Becker Oven—The Koppers-Becker oven employs a different flue arrangement whereby the gas is burned on an entire wall simultaneously (both pusher and coke side). The products of combustion from groups of two or more vertical flues of the "on" walls in which the fuel gas is burning enter short bus-flues and are thence conducted over the top of the oven through cross-over flues to a companion series of bus-flues whereby the entire "off" wall is simultaneously conducting waste gas to the regenerators. On reversal, the opposite conditions obtain. Since the flues in each wall (coke side to pusher side) are connected only to the flues in its companion wall, there are no crossover flues over every other oven and the battery thus is limited to an uneven number of ovens (see Figures 4-7 and 4-8).

The Wilputte Oven—The Wilputte oven is known as a double-divided oven, having two outer zones in the heating system and one double inner zone. In this oven, the gas is alternately burned upwards in the two outer zones with the products of combustion being carried down through the double inner zone and, on reversal, burned upwards in the double inner zone with the products of combustion being carried down through the two outer zones (Figures 4-3, 4-9 and 4-14).

The Semet-Solvay Oven—The Semet-Solvay installations have oven batteries employing horizontal heating flues (the other three types use vertical heating flues), wherein fuel gas is introduced at one end and waste gas drawn off at the other end, with regular reversal of flow (Figures 4-3 and 4-10).

SECTION 4

CONSTRUCTION AND OPERATION OF BY-PRODUCT OVENS

For purposes of discussion, the different principal parts of a by-product oven will be considered in the following order; i.e., Coking Chamber, Heating System, Oven Doors, Gas-Collecting System, and Accessory Equipment.

Coking Chamber—The dimensions of the coking chamber are in each case a compromise of many correlated variables that will best suit the expected operations and produce the highest grade of product within practical limits. Past experience with coals of similar properties is the best guide, as there is no well defined academic method of arriving at definite oven dimensions for specific coals.

In general, the average dimensions of the present day oven are from 10 to 14 feet in height, 30 to 43 feet in length, and 15 to 19 inches in average width. The ovens are narrower on the pusher side and have a taper of from 2 to 4 inches, according to the expanding or contracting properties of the coals to be coked. The ends of the oven are closed with brick-lined removable doors. The side walls, or liners, are built of first-quality silica-brick shapes set in silica mortar that forms a ceramic bond at the higher temperatures. The oven floor may be of first-quality clay blocks, though silica bricks have been used for oven floors for many years.

Inasmuch as most of the heat for the coking process is conducted through the oven liners, the coking really starts at the side walls and progresses through to the center of the coal charge. There is no fusing together of the charge at the center as can be seen in Figure 4-11. This feature limits the length of any piece of coke to half the width of the oven minus any shrinkage. The structure of the coke mass at the end of the coking period is somewhat similar to two parallel slabs of irregularly interlaced pieces of coke that may be pushed from the oven by the pressure applied by the pushing ram with very little lateral pressure on the oven side walls. However, the walls must have sufficient structural strength to resist a high lateral pressure in case the interlaced structure of the coke mass is broken up for any reason during pushing. All modern ovens, from a structural point of view, also are designed to prevent, as far as possible, leakage of gases in either direction through the brickwork between the oven retort and the heating flues.

For a brief period after the establishment of this by-product coke oven in the United States, there was a trend toward using narrow ovens, but the modern trend for most plants is towards use of wider ovens. There is also a trend toward more taper, pusher to coke side, in the oven chambers. This increased taper permits the use

FIG. 4-11. View of coke being pushed from oven, showing central line of cleavage and block-like structure of the coke.

of a wider range of coals of varying characteristics, allowing for greater flexibility in making up blends for charging ovens whenever changing blends becomes necessary to utilize coals other than those normally used. In this way irregular blends may be processed with less danger of damage to the ovens or excessive operating delays by causing stickers.

Stickers are ovens that cannot be pushed in the normal manner due to excessive expansion during the processing, or coke of insufficient structural strength to hold the interlaced mass during pushing, thereby developing a lateral component of the pushing force that greatly increases the side-wall friction.

The coal is charged into the oven through charging holes provided in the roof of the oven. The oven retort and the heating system are designed for a coal charge of definite volume, having a level top surface a definite distance below the oven roof, usually one foot. The number of charging holes and the physical characteristics of the coal have a definite bearing on the time required for charging the oven with coals. A minimum charging time is particularly desired for many reasons. To prevent escape of gases from the oven during charging, it has now become standard practice at most plants to charge the oven on the main. As charging on the main is accomplished by steam-jet aspiration, which puts the oven retort under suction during the charging and leveling period, it is impossible to prevent the introduction of some air into the gas recovery equipment.

Excessive leveling tends to pack the coal along the top of the coal charge, particularly under the charging holes thus increasing the bulk density and heat requirements at this area. This has particular significance when using expanding coals. Excessive leveling may also cause local erosion of the oven wall.

Heating System—The present-day heating systems of the more prominent ovens in this country fall into two general classes; the **gun-flue type**, shown in Figures 4-12a, b and c, and the **underjet type**, shown in Figures 4-13 and 4-14. In the gun-flue type the gas is introduced through a horizontal gas-duct extending the length of each wall a little below the oven floor-line. Short connecting ducts lead vertically upward to a replaceable nozzle-brick at the bottom of each of the vertical flues. In the underjet type, the fuel gas is introduced into each flue from the gas distributing piping in the basement of the battery through a circular gas duct built integrally into the regenerator division and flue supporting walls. Each of these separate burner pipes is equipped with an orifice and metering pin to permit control of gas to each flue.

There are various designs of both general types, all attempting to heat the coal as charged at a controlled rate and temperature, uniformly from end to end of oven, and from bottom to top of charge (with the exception of the top few inches which may be held slightly lower for the better control of coal-chemical recovery), and at the lowest rate of Btu's per pound of coal carbonized. In the Koppers oven of 1917, as previously described, the coke-oven gas, stripped of various coal chemicals, is burned in all flues on the pusher side at once, the products of combustion passing into the horizontal flue and then down through the coke-side flues and regenerators to the stack. On reversal, the air is preheated in the coke-side regenerators and burns the gas in the coke-side vertical flues. The products of combustion are conducted through the horizontal flue to the pusher-side flues where they are carried down through the pusher-side regenerators and to the stack. In the Koppers-Becker ovens the arrangement of the regenerators beneath the ovens, as shown in Figure 4-15, is such that the ovens under the cross-over ducts have alternately one wall with gas on and one with gas off, while the ovens not under cross-over ducts have alternately both walls with gas on, and then both with gas off. This regenerator arrangement is in the interest of having a minimum number of walls operating under high differential pressure. Considerable care is taken in design to have the lowest possible differential pressure between the flues and ovens and between adjacent regenerator walls in order to prevent cross flow of gases at these locations.

Another point in flue design of particular importance is the relative position of the gas inlet in the vertical flue in relation to the air port, and the manner in which the gas and preheated air are caused to be mixed. Excessive turbulence will result in too sharp combustion, and a short intense flame will cause local over-heating at the base of the vertical flue.

For many years, oven operators and designers have felt that control of the rate of flame propagation and flame length in the vertical flues was desirable. Many suggestions were considered, the principal one of which was waste-gas dilution. The difficulties and expense associated with the use of waste gas that had been permitted to cool below the dew point were prohibitive. A system of waste gas recirculation by jet aspiration has been used in the Koppers-Becker design (see Figure 4-16). By this device a fixed amount of hot, waste gas is mixed with the incoming fuel gas. By this recirculation used in the Koppers-Becker design (see Figure 4-16), a fixed amount of hot waste-gas is mixed with the incoming fuel gas. By this recirculation the flame length may be controlled without purification of the waste gas and without having to heat the diluent as would be required with external mixing. The ratio of recirculated

waste-gas to oven gas is controlled by the orifice size and the fuel-gas pressure, and normally approximates a one-to-one mixture.

Waste-gas recirculation also prevents the accumulation of carbon in the underjet gas-ducts, as the contained carbon dioxide and water vapor both tend to inhibit carbon deposition. In ovens not recirculating waste gas, air must be introduced into the gas ducts on the "gas off" periods for decarbonization.

A feature of the Wilputte oven, shown in Figures 4-3, 4-9 and 4-14, especially those of over 10 feet in height, is the high-low burner construction. Low burners in alternating flues with adjacent high burners prevent overheating at the bottom of the flues and thus tend to give a better vertical distribution of heat.

In the gun-flue-type oven, the changes of the nozzle brick which regulate the gas flow to the various vertical flues is done from the top of the battery. Immediately over each vertical flue, a duct is provided from the horizontal flue through the battery top and ending at a removable flue-inspection cap flush with the oven top. When necessary, the nozzles are removed and replaced through these ducts by long rods especially designed for this purpose. In the underjet-type oven, the same flue extensions are provided for flue inspection, but the gas flow is regulated by changing the orifice or metering pin in the accessible external fuel-gas piping in the oven basement.

Where blast-furnace gas or other lean gases are used for oven heating, the regenerator system must be designed so that both the air and gas are preheated. In the Koppers-Becker oven, the regenerator chambers are so arranged that the fuel gases and waste gases are not regenerated in adjacent chambers but are separated by an air-regenerating chamber. With this design, the effect of leakage across the high-differential pressure wall is minimized, as the incoming air and gas are under the same pressure and traveling in the same direction, and the high-differential-pressure wall is between the incoming air and the outgoing waste-gas.

When a lean gas, such as blast-furnace gas or producer gas, is used for oven heating, supplementary heating with a higher calorific value gas may be needed in order to maintain coke production at as high a rate per oven operating hour as when firing with straight high-Btu gas. It is not practical to do this mixing before regeneration of the gas as the rich component of the mixed gas will be partially cracked passing through the regenerators and will cause an objectional deposition of carbon. To overcome this cracking tendency, the enriching gas is externally diluted to the desired degree with lean gas and introduced through the customary fuel system.

With the introduction of the underjet oven and the accurate proportioning of fuel gas necessary to each vertical flue, it is important that the reversing cocks,

FIG 4-14. General perspective "cut-away" drawing of a Wilputte combination underjet-fired by-product coke oven. The "rich" fuel gas referred to is coke-oven gas; the "lean" fuel gas is blast-furnace gas. Compare with Figures 4-3 and 4-9. (Courtesy, Wilputte Coke Oven Division, Allied Chemical and Dye Corp.).

lines, and orifices or metering pins be clean at all times. This is accomplished by cleaning the fuel gas with electrical precipitators located at each battery of ovens.

After the electrical precipitators, and ahead of the battery fuel-gas mains, the gas is heated to assure its maintenance above the dew-point. On some of the older designs of the gun-flue type, the fuel-gas mains located in the alleys on both the pusher and coke side were insulated to limit the condensation in the headers and to keep the gas at a uniform temperature throughout the length of the header. This temperature control is important as temperature change affects the density and specific heat of the gas and influences the uniformity of battery heating.

In the gun-flue-type oven, the air required for combustion is taken into the sole flue at the base of the regenerator chambers through an air box equipped to regulate the amount of air taken from the alleys on both sides of the battery. In this arrangement the temperature, the velocity and direction of the wind have a marked effect on the heating and must be compensated for by the heater. In the underjet type, the air for combustion is taken from the enclosed basement and is independent of atmospheric wind velocity, direction, and temperature.

In the Wilputte design of underjet ovens, the basements are sealed and kept at a constant air pressure (slightly above atmospheric) by sensitive controls, with only the air required for combustion entering the basement through a wind tunnel extending along the entire length of the battery. A fan of sufficient size delivers air to the wind tunnel. Spaced along the length of the basement are suitable openings equipped with regulating louvers to distribute the air uniformly throughout the

basement. In this design, only the air required for combustion is available for basement cooling.

In Koppers-Becker underjet-type ovens of a recent design for large batteries, the air for combustion is introduced in much the same manner as that just described, with the exception that from two to three times the air required for combustion is forced into the basement, the excess finding its way out through suitable openings around the buckstays on the pusher side (the wind tunnel being on the coke side of the basement). In this arrangement, from two to three times the air required for combustion is circulated through the basement for cooling. In still later designs of this type of oven, only the amount of air required for combustion is introduced into the basement.

The effects of faulty heating may be serious, not only to the quality and quantity of the coke and coal chemicals produced, but also to the ultimate life of the ovens. The most serious damage to the ovens is local overheating beyond the critical temperature of the exposed brick, when fluxing or slagging occurs. This usually occurs in zones that are not readily accessible for repair. The advantages of an even and controlled heat throughout the oven cannot be overemphasized and remains a constant challenge to the engineer.

When a new battery, or an old battery that has been allowed to go cold, is to be put into operation, great care must be taken in bringing the battery up to operating temperature. Since the major portion of the battery is of high-grade silica-brick construction, and silica brick has a high coefficient of thermal expansion at lower than operating temperature, it can readily be seen that the heating up must be slow enough to insure maximum temperature equalization throughout the entire battery

FIG. 4-15. Longitudinal sections through part of a battery of Koppers-Becker combination underjet low-differential by-product coke ovens of the type illustrated in Figure 4-13. Figure 4-16 shows further details. (Courtesy, Koppers Company, Inc.).

structure. In actual practice, the heating up from cold to carbonizing temperature takes from five to seven weeks. This same practice obtains in reverse when it is desired to allow a battery of ovens to go out of operation and cold. The cooling of the battery is a project to be undertaken only after full appraisal of all alternatives.

The usual method of heating up a battery is first by installing a temporary brick door at each end of each oven and burning gas in a burner inserted in the oven through an opening provided in the temporary door. The products of combustion are allowed to enter the heating system at the horizontal or bus-flue elevation through suitable openings provided for this purpose, which are later plugged and sealed. The hot gases during the drying-out period are vented down through the vertical flues and regenerators to the stack flue and stack. When the flues become hot enough to ignite fuel gas on reversal, the gas is introduced through the normal channels. Where gas is not available for heating up, coal or coke may be used by substituting a brick bulkhead for the oven door, leaving openings for firing and ash removal. The same type of false hearth is used to protect the oven liner-brick. After heating up, the false hearth and bulkhead are removed, and the oven door is installed.

FIG. 4-16. (Top) Enlarged detail of an underjet gas-duct and air-port, and (Bottom) section through waste-gas recirculation duct of the Koppers-Becker by-product coke ovens shown in Figure 4-15. (Courtesy, Koppers Company, Inc.).

Many controls of the heating system are fixed in that they are built into the oven structure. The means of variable control are comparatively simple and to a great extent similar in all the modern ovens of the same type. In general, they consist of gas-pressure control in the headers; the size of nozzle, orifice, or metering pin used in the connections to the individual flues; stack-draft controls for the main stack-flue and for the individual ovens; combustion-air controls; various temperature controls and pyrometers.

Oven Doors - As has been mentioned, the ends of the oven are equipped with removable refractory-lined doors. After a coal charge is fully coked and the oven dampered off the main, suitable equipment on both the pusher and coke sides remove the doors and hold them during the pushing operation. After pushing, the doors are replaced and sealed preparatory to recharging the oven.

Until recent years, the method of sealing the doors was to trowel and smooth ground "mud" into a V-shaped opening between the door and the door jamb. In recent years there have been developed self-sealing doors that do not require luting. In principle, the self-sealing door has finally developed into a spring-loaded door that depends on a metal-to-metal contact between the door and the continuous machine-surfaced cast-iron jamb. The Wilputte design of self-sealing door is shown in Figure 4-17. The sealing edge of the door is carried by a flexible frame, and the door assembly is so designed that a powerful spring between each locking bar and the door forces the sealing edge against the metal door jamb with considerable pressure, thus preventing the escape of volatile products from the oven. The pusher-side door

FIG. 4-17. Wilputte design of self-sealing coke-oven doors, showing spring-loaded bars that maintain metal-to-metal contact between the door and jamb. (Courtesy, Wilputte Coke Oven Division, Allied Chemical and Dye Corp.)

is also equipped with a somewhat similar small self-sealing door to permit leveling of the coal as charged and removal of any excess coal.

Oven-door expense is a large factor in over-all oven repair and maintenance costs. This expense can be controlled by careful design of door-handling equipment and strict adherence to good operating practice. The lining of the door is usually sectionalized and made up of clay-brick shapes. In some plants the doors have a monolithic lining of lumnite cement made with an aggregate of various grades of crushed brick and ganister which give good service. The thickness of the lining, and the position of the inside face of the lining relative to the end vertical flue of the oven is important as it influences the heating of the ends of the coal charge.

Gas-Collecting System—The oven may be equipped with one or two offtakes to carry off the volatile products liberated in the coking process. Where one offtake is provided, it is through the roof of the oven at either end of the oven, and where two are provided, there is one at each end of the oven. In either case the volatile products pass through the duct or ducts in the oven top and enter a refractory-lined standpipe which in turn is connected to a collecting main through a damper-valve. Between the damper-valve and the oven the standpipe is equipped with a cap valve, marked "elbow cover" in Figures 4-18 and 4-19, which, when open, vents the oven to the atmosphere. The use of a double or single collecting main is still a question of no little debate among coke-plant operators, each system having its advantages.

The damper valve is usually a water-sealed valve, so designed that the cooling spray furnishes the seal when the damper valve is in the closed position, the excess spray overflowing into the collecting main. With this arrangement, the cooling spray is always on. The water, called **flushing liquor**, used in damper box and collecting-main flushing, is the condensate from the volatile

FIG. 4-18. Water-sealed damper valve of the design employed by Koppers Company, Inc., through whose courtesy this drawing is reproduced.

FIG. 4-19. Wilputte design of water-sealed damper valve, incorporating a Corliss-type valve in the bottom of the damper box. (Courtesy, Wilputte Coke Oven Division, Allied Chemical and Dye Corp.)

products driven off in the coking process. This water is later processed by the coal-chemical division for the recovery of ammonia. Figure 4—18 shows a design of water-sealed damper valve as built by Koppers Company, Incorporated. The Wilputte design, which may be seen in Figure 4—19, is somewhat different in that the valve is sealed by closing a Corliss valve in the bottom of the damper box which permits the spray to fill the box, thus sealing the damper. In addition to the wet type dampers, two dry type (not spray sealed) are in use at various plants; namely "dry butterfly" and the "mushroom" valve. All ovens of a battery are thus connected to a single or multiple pressure-equalized collecting main on either or both sides of the battery.

The function of either the single or double collector main is not only to collect the gas from the ovens but also to maintain at all times an accurately-controlled pressure in the oven during the coking process. Pressure in the oven during coking has a pronounced effect on the coke and coal chemicals. The pressure in the collecting main is usually kept at a point that will give about 1 mm. water-gage pressure at the bottom of the oven at the end of the coking period. It should not vary over plus or minus 1 mm. of water-gage pressure. The pressure is controlled by a regulator, usually of the Smoot or Askania type, located in the connection between the collecting main and the suction main which carries the gas to the coal-chemical recovery units. The collecting main also serves as a receiver for the products condensed from the gas by the flushing liquor.

Recent installations of Koppers-Becker underjet batteries have been designed for control of the temperature in the gas space above the coal charge. This has been accomplished by recirculating cooled raw coke-oven gas across the top of each oven above the coal charge by an artificially induced differential pressure between the pusher-side and coke-side gas-collecting mains. This differential pressure is provided by variable speed fans installed in the cross-over main connecting the two gas-collecting mains. On some predetermined cycle the dif-

ferential pressure is reversed to keep the pusher-side and coke-side temperatures in the oven tops in proper balance.

The use of a patented principle, in which gas from newly charged ovens (in which a relatively high pressure exists) is drawn off and passed through the space above the charge in ovens nearing the end of their coking periods (in which pressures are lower than average), is incorporated in ovens of recent Wilputte design. It is applied to ovens with double collecting mains, one main being used alternately with the other as a compensating main. In effect, one main is employed as a suction main on one side of the battery, with the other acting as a connection between the ends of all of the ovens on the other side of the battery, to assist in equalizing pressures in the spaces above the charges. These functions are reversed periodically. In addition to aiding in control of pressure in the ovens throughout a battery, the system also affords control of temperature throughout the tops of the oven chambers to prevent overheating of the gas space. The alternate use of each main as a suction main makes it possible to cause gas flow in either direction through the ovens near the end of their coking cycle so as to prevent overcooling in any particular area. In general, this system provides the same benefits as that described in the preceding paragraph, but by a different method.

The gas, on entering the damper box, or, in the case of dry dampers, the collecting main, is shock cooled with a liquor spray which causes the first precipitation of tar from the gas. The amount of liquor sprayed is important, as it controls the temperature to which the gas is cooled. Too little cooling allows only the heavy tars to precipitate, which may cause pitch deposits in the damper box and collecting main. Too much cooling may throw down too much light tar, and may result in naphthalene stoppage in the primary coolers or difficulty in tar dehydration. Some plants are equipped to permit segregation of the tar condensed in the collecting and suction main as opposed to that condensed in the primary coolers.

SECTION 5

ACCESSORY OVEN EQUIPMENT

Coal-Storage Bins and Charging Larries—To provide coal for the ovens, every modern plant has an overhead coal bin at the ovens of sufficient surge capacity to permit flexibility in coal preparation without interference to the scheduled uniform operation of the ovens. The number and size of bins required is determined for each individual plant. The location is determined from a study of each plant's layout of operating units.

All modern by-product coke ovens are designed to take a definite volume of coal per charge and are charged from a larry car operating between the overhead coal-storage bins and the ovens on a track supported by the battery top. Figure 4—20 is a view of a battery top, and shows a larry car.

The desired amount of coal for an oven charge is drawn from the storage bin, and is measured, usually by using either the track scales at the loading station, or by volumetric choke boxes on the larry car. Where track scales are used, the coal-bin gates over each hopper of the larry are usually hand operated. Where the separate hoppers of the larry, one for each charging hole, are equipped with volumetric choke boxes, the gates are usually linked together and power operated as all gates may be left open until the hoppers are full and the flow of coal is stopped by the choke boxes.

The larry car in principle is designed in connection with the number of charging holes per oven so that a predetermined quantity of coal is charged into the oven through each charging hole, the discharge from each hopper being independently operated, either manually or by power.

Improvements in larry cars, particularly the method of discharging coal, have been directed toward making possible better charging practices. The aim has been to reduce the charging time; to reduce the number of passes of the leveling bar necessary for leveling; to make a smokeless charge; to prevent hanging up of the coal in the larry hoppers; and to make a uniform charge as regards bulk density.

The gravity-discharge larry and the mechanically-unloaded larry are the two main types in use at the present time. The gravity-discharge larry is equipped with conical-shaped hoppers, shear gates and drop-sleeve mechanisms. Vibrators attached to the hoppers and stainless-steel liner plates may or may not be provided, depending upon the physical condition and flow characteristics of the coal. With this type the coal charge flows by gravity into the ovens. There are two designs of mechanically unloaded larry cars in use at present; namely, the "turntable" and "screw discharge" types.

Fig. 4 20. Larry car equipped with screw conveyor for discharge of coal into ovens. The battery shown is fitted with double collector mains.

The turntable larry is equipped with a revolving table serving as the bottom of each hopper. The revolving table forces the coal through an opening in the side of the hopper leading to the shear gate and drop sleeve and thence to the oven. The screw-discharge larry is equipped with rectangular-shaped hoppers with the lower section tapering to a small opening directly over the screw trough. The trough contains the screw conveyor which forces the coal horizontally to the vertical drop sleeve and shear gate section. The hoppers are lined with stainless steel if adverse flow characteristics of the coal are encountered.

The screw-discharge larry gives a slightly better performance on wet or fine coal but considerable difficulty is encountered with any foreign matter in the coal, whereas the gravity-discharge larry and turn-table larry have less trouble with foreign matter in the coal. The gravity-discharge larry gives slightly more trouble with fine or wet coal than either of the other two types. The screw-discharge larry and the turn-table larry have much greater initial cost and greater total weight which is a source of potential damage to oven brickwork. The gravity-discharge larry is the least expensive initially and is the lightest of the three types. The screw-discharge larry is the most expensive to maintain, and the gravity-discharge, with vibrator and stainless steel hoppers, the least expensive to maintain.

Pusher-Side Equipment—The pusher-side equipment shown in Figure 4—21 is generally similar on all

types of ovens. The pusher may be a combination of three machines, a **pusher**, a **leveler**, and a **door extractor** so designed that it operates on a track parallel to, but independent of, the battery. In many plants, the door-handling equipment is a separate, self-propelled machine, operating on its own tracks.

The function of the door-extracting element of this machine is to remove and hold the pusher-side door during the pushing operation. It is either electrically and/or hydraulically operated from the elevated cab which contains all the machine controls. With self-sealing doors, an important feature of the door-extractor design is that its speed be relatively slow and easily controllable and the alignment be accurate to avoid damage to the sealing edges of the door. Contained in the head of the extractor is a mechanism for latching the door and for compressing the loading-springs.

The function of the pushing element (Figure 4—22, Diagram E) is to push the coke cake from the oven. This is done by an electrically-powered rack-and-pinion-operated ram, equipped with a suitable head that, when spotted immediately in front of the oven to be pushed, may be moved forward until all the coke has been pushed from the oven and through the coke guide into the quenching car.

The ram is equipped with a rider-shoe located about 5 feet behind the pushing head to support the ram during its passage through the oven. This rider-shoe is easily replaced as it is subject to considerable abrasion

FIG. 4-21. Pusher-side equipment of a battery of by-product coke ovens, showing the machine which is equipped to level the coal charge in the oven and also push the finished coke out of the oven, as well as remove and replace oven doors before and after the pushing operation.

sliding over the brick floor of the oven, especially as there is always considerable coke breeze on the oven floor during the pushing and return. The ram is either a built-up box girder, "H" beam, or open-lattice electrically-welded structure. The open-lattice construction seems to be currently in favor as it is more easily repaired and resists the tendency to warp, due to more even cooling, regardless of wind direction. With the box-girder-type ram, it is necessary to have wind-and-rain guards for the ram in its retracted position. The pushing speed of the ram is about 60 feet per minute, and the maximum pressure exerted is controlled by overload relays to prevent damage to the oven brickwork.

The function of the leveling element (Figure 4-22, Diagrams B and C) is to level the coal charge in the oven, leaving a free-gas space below the roof of the charged oven. This is done by an electrically-operated leveling-bar carried by the pusher-machine structure in such a position that it may be introduced through a suitable opening in the top of the pusher-side door. The leveling-bar is a fabricated section consisting of two side-plates held apart by vertical plates spaced at from 2 to 4 feet which also serve as scrapers. When this bar is moved in and out of the oven, the scraper plates level the humps of coal into the valleys and, on removal from the oven, drag out all excess coal into a chute discharging into a receiving bin carried by the pusher machine. This excess coal is periodically dropped into a ground-level hopper for return to the coal bunker. At some plants, the excess coal is returned by a conveyor to the next oven charged.

The various platforms, control rooms, and operating cab of the pusher machine should be designed to facilitate comfortable operation and accessibility for oiling, adjusting, and repair. Inasmuch as the three principal operations of the pusher machine always occur separately, one operator is all that is required. However, men known as door and jamb cleaners accompany the pusher and, in most cases, they also open and close the leveling door from the oven pusher-side bench and clean up any coal and coke spillage.

Where self-sealing doors are not used, it is necessary to provide equipment for the preparation of luting mud and for conveying the luting mud to the doors to be luted. The mud is usually prepared in the conventional-type wet pug mill from returned luting mud, coke breeze cleaned from the oven benches, and certain amounts of fresh clay. The mud buggies, or carriers for the pusher side, are usually electrically-operated and suspended from an overhead track, and are equipped with bins and platforms at two or three levels, according to the oven-door height, so that the luterman can easily trowel the mud required to seal the oven door.

With self-sealing doors a motorized buggy is sometimes provided to facilitate manual cleaning of doors and door jambs. Recently-developed buggies are equipped with elevators and heat shields.

The pusher side of the battery is equipped with a bench serving as a walkway along the entire length of the battery and as a working platform for men serving the pusher-side doors and jambs. Until recent years, the level of this bench was a few inches below the level of the oven floor and could not be protected by hand rails

CHARGING, LEVELING AND PUSHING OPERATIONS IN ONE COKING CYCLE OF A BY-PRODUCT COKE OVEN

- A. THE CHARGING LARRY, WITH HOPPERS CONTAINING MEASURED AMOUNTS OF COAL, IS IN POSITION OVER CHARGING HOLES FROM WHICH COVERS HAVE BEEN REMOVED. THE PUSHER HAS BEEN MOVED INTO POSITION.

- B. THE COAL FROM THE LARRY HOPPERS HAS DROPPED INTO THE OVEN CHAMBER, FORMING PEAKED PILES.

- C. THE LEVELING DOOR AT THE TOP OF THE OVEN DOOR ON THE PUSHER SIDE HAS BEEN OPENED, AND THE LEVELING BAR ON THE PUSHER HAS BEEN MOVED BACK AND FORTH ACROSS THE PEAKED COAL PILES TO LEVEL THEM. THE BAR NEXT IS WITHDRAWN FROM THE OVEN. THE LEVELING DOOR AND CHARGING HOLES ARE CLOSED, AND THE COKING OPERATION BEGINS.

- D. COKING OF THE COAL ORIGINALLY CHARGED INTO THE OVEN HAS BEEN COMPLETED (IN ABOUT 18 HOURS) AND THE OVEN IS READY TO BE "PUSHED." THE OVEN DOORS ARE REMOVED FROM EACH END, AND THE PUSHER, COKE GUIDE AND QUENCHING CAR ARE MOVED INTO POSITION.

- E. THE RAM OF THE PUSHER ADVANCES TO PUSH THE INCANDESCENT COKE OUT OF THE OVEN, THROUGH THE COKE GUIDE AND INTO THE QUENCHING CAR.

FIG. 4-22. Schematic representation of the sequence of operations involved in charging, leveling and pushing in one coking cycle of a by-product coke oven.

FIG. 4—23. Door-extracting machine and coke guide operating on tracks on the coke-side bench of a coke-oven battery.

in any practical manner on account of clearance for the pusher ram. It is now general practice to lower the bench about $2\frac{1}{2}$ to 3 feet below the oven-floor level so that the pusher ram may pass over the top of a railing. The benches are similarly lowered on the coke side.

The main operating units referred to above, and their functions, are illustrated schematically in Figure 4—22.

Coke-Side Equipment—The coke side of the battery is equipped with a door-extracting machine, coke guide, and, when using luted doors, a luting buggy. The coke-side equipment operates on a track integral with the coke-side bench, as shown in Figures 4—22 to 4—24, inclusive.

The function of the door machine is to remove and hold the coke-side door during the pushing of an oven and to place an attached coke guide in the proper position to conduct the coke across the bench into a quenching car operating on a ground level track which is parallel with the battery.

The design and operation of the door extractor is generally similar to the door extractor of the pusher machine. Recent developments place the extracted door behind a heat shield and have details of design that facilitate easy door cleaning.

The coke guide is attached to the door-extractor machine by a disconnecting coupler. It is conducted along the coke-side bench. At modern plants, the coke guide is equipped with a movable lattice framework that is

power-operated from the door machine. When spotted at the oven to be pushed, this movable framework is moved into the space between the buckstays and against the door jamb, thus preventing coke spillage at this point during pushing. As this part of the guide is subject to the greatest wear, it is designed for ease of replacement and is constructed of metal that will resist heat and wear.

On plants using luted doors, the coke side is provided with motorized luting buggies, generally similar in design and operation to the pusher-side luting buggies.

Quenching Station—There are two methods of quenching the hot coke that is pushed from ovens, namely, wet quenching and dry quenching, the latter being used more extensively in European countries than in the United States. All but one or two plants in the United States wet quench, principally for economic and operational reasons. In dry quenching, this sensible heat is used for the production of steam for general plant use; this will not be discussed here, except to state that it is accomplished by dumping the hot coke into a closed system where the recirculation of inert gas conducts the sensible heat from the coke to a low-pressure boiler until an equilibrium is reached within practical limits, and the coke is below the ignition point in air, at which time the coke is discharged for screening and loading.

Wet quenching in most modern plants is accomplished by receiving the charge of hot coke from the ovens in

FIG. 4—24. Coke side of a battery of by-product coke ovens during the process of pushing the coke out of one of the ovens. The quenching car is self-propelled, and carries the coke to a quenching station where it is sprayed with water before being dumped on the coke wharf.

the quenching car, which is conducted to a quenching station by an electric locomotive, where it is quenched with water. The car is then taken to a coke wharf where the coke is discharged. The handling of the coke from the wharf will be discussed later.

The quenching car is designed so that by moving the car during the pushing operation the coke is caught in a relatively uniform bed about two feet thick on the sloping bottom of the car (Figure 4—24). The power-operated gates, either electric or air, at the low side of the sloping bottom are so designed and arranged that the quenching water not evaporated may readily drain from the car. When the charge of hot coke has arrived at the quenching station, it is spotted under a system of stationary sprays located in the quenching tower. The operator starts the quench by remote control. The purpose of quenching is obviously to rapidly cool the coke to stop any further combustion. However, it must be recognized that coke of low-moisture content is desired. This is accomplished by so arranging the sprays and the time of quench that sufficient heat will remain in the center of the individual coke lumps to dry excess surface water. The usual practice is to aim at 2½ per cent average moisture in the metallurgical coke after screening.

Most modern plants, of necessity, quench with contaminated water as there seems to be no other practical method of disposal of these waters. It is therefore necessary to design the quenching station in such a way that all such waters can be recirculated until evaporated. This is done by pumps delivering water from a contaminated water sump to the spray lines and returning the unevaporated water to the sump. Any makeup above the plant production of contaminated water is fresh water.

Instrumentation and Control—Most instrumentation around the ovens is confined to the heating facilities. As has been mentioned, the variable controls of individual ovens of a battery are so adjusted that master controls may be installed for each battery of ovens. In

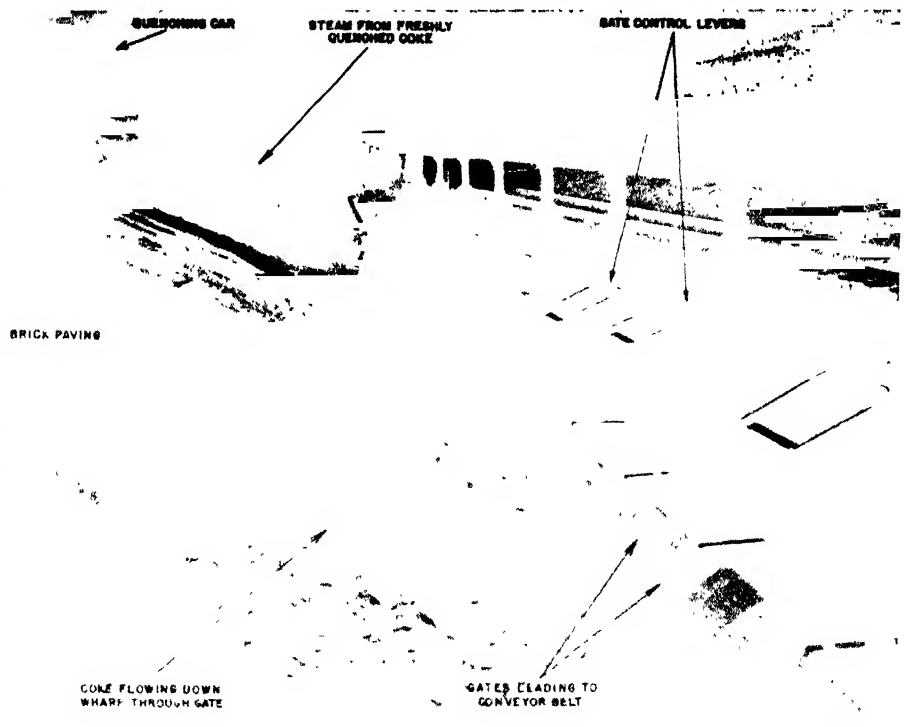

FIG. 4—25. General view of a coke wharf, showing freshly quenched coke being discharged from the gates of the quenching car onto the brick-paved, sloping wharf. When the wharf gates are opened, coke slides down the wharf as at the lower left onto a conveyor belt that carries it to the screening station.

this manner, single machines, meters, gages, and other devices control the various functions of the battery heating system after the individual-oven controls have been adjusted and connected. Thus, the gas required for underfiring is metered in the battery header only. The choice of a flowmeter for this service will be influenced in large part by its accuracy over a wide range of flow. The meter should be recording, preferably one adapted to a uniform graduated chart for reasons of legibility and computation facility. It is also necessary to control accurately the pressure in the fuel-gas main with an instrument capable of close control at relatively low pressures. It may be desired to have a recording of these pressures. A recording thermometer is also installed in the fuel-gas header so that the gas quantities may be computed to standard conditions. The battery is also

equipped with recording draft gages, waste-heat recording thermometers, and various indicating gages. Portable pressure gages, thermometers, and pyrometers are used in the setting of individual-oven controls. Another instrument used by the heaters is a portable pyrometer with which periodic temperature readings are taken of the flues and emerging coke. Probably the most widely accepted pyrometer is of the incandescent-filament type. Recording pressure and temperature gages are also installed in the gas-collecting mains.

Many plants record the regularity of oven operation by some related activity, such as the time of pushing, by the peak-load recording of the pushing-power circuit, or by a recording of the time of quenching of each charge. All utilities have the usual types of instrumentation.

SECTION 6

COKE SCREENING AND HANDLING

Coke Wharf—The coke wharf receives the quenched coke from the quenching car where it is spread out in a thin bed for quick drying and visual inspection for unquenched coke. For obvious reasons such spots must be hand quenched before it is conveyed on rubber belts to the screens. Figure 4—25 shows a view of a modern coke wharf. It is substantially a long, narrow inclined platform with the shorter dimension sloping away from the quenching-car track towards a belt which runs along the lower side of the structure. A properly designed wharf should be of such size that it will serve as a surge storage for quenched coke ahead of the screens so that short delays incidental to screening and loading operations will not interrupt the desired regularity in oven-pushing sequence. Most modern wharfs are paved with hard-burned clay brick, although some plants use cast-iron plates and even refractory concrete for the purpose.

The coke is retained on the wharf by a series of hand-operated gates which, when opened, permit the coke to slide down the wharf and onto the belt conveyor to be delivered to the screening station.

Conveyor System for Coke—The transfer of coke from the wharf to the screening station is accomplished now almost universally by a system of rubber-belt conveyors and chutes.

Screening and Crushing—The purpose of coke screening and crushing is to provide a controlled size of coke for blast-furnace use from which fines and, in some cases, pieces over a set maximum size, are removed. The latter are crushed and screened before use. The very small sizes, commonly called coke breeze are usually used in the coke plants as a boiler fuel or screened for domestic trade.

Storage and Shipping—In the loading of furnace coke and the subsequent transportation to the blast furnaces, care must be taken to prevent additional breakage. For this reason, the coke is loaded into railroad cars and, where practical, is consigned directly to the blast furnaces, as additional handling into and out of stock results in inevitable coke degradation. Where the blast furnaces are located close to the coke plant, belt conveyors are often used to conduct the coke from the screening station to the blast-furnace bins.

SECTION 7

LIMITATIONS AND FUTURE OF BY-PRODUCT COKING

Perhaps the most important over-all consideration that should be kept continually in mind in designing by-product coke ovens and the various auxiliary equipment is that the great majority of design features incorporated in the battery construction cannot be altered during the 20 to 30 years of battery life. It is, therefore, imperative that design as well as construction be of the highest quality. While theory must naturally play an important part in this design, it is well not to overlook the fact that, since the coking characteristics of the coals to be used have such a vital effect on oven design, empirical data developed from actual experience with similar coals is invaluable.

While it is true that the great majority of design work required for by-product coke-oven construction is necessarily carried on by the builders, the engineering work

required of the operating company and plant organizations is of sizable amount and of tremendous importance. In the first place, the builders of coke ovens have always been extremely receptive to suggested improvements, and many have been incorporated in modern oven construction. Secondly, there is considerable latitude in the selection of type and size of ovens, in auxiliary equipment, and particularly in facility layout, all of which require intelligent action on the part of the operating company. And finally, the incentive to produce products of higher quality at reduced costs, coupled with the experience gained through actual operation, repair, and maintenance of the by-product coke-oven facilities, places the organizations of the operating companies in an increasingly important position in furthering the advancement of coke-plant design.

Chapter 5

RECOVERY COAL OF CHEMICALS

SECTION 1 INTRODUCTORY

Chemical Nature of Coal—Coal is the remains of vegetable matter which has been partially decomposed in the presence of moisture and the absence of air and subjected to variations in temperature and pressure by geologic action (see Chapter 3). It is a complex mixture of organic compounds, the principal elements of which are carbon and hydrogen with smaller amounts of oxygen, nitrogen, and sulphur. The ash consists primarily of inorganic compounds which became imbedded in the coal matrix during the coalification process.

The molecules making up coal are basically composed of groups of hexagonal carbon rings with attached hydrogen atoms. In addition, some five-membered carbon rings and carbon chains are attached to the six-membered carbon rings. The chemical structure may be pictured as an aggregate of "mosaics" consisting of cyclic groupings of carbon and hydrogen with six-membered rings and side chain linkages; multi-molecular structures in which component rings are joined together. These compounds like most of those in animal and vegetable life are unstable when subjected to a high degree of heat or thermal treatment.

Since coal may be considered as a hydrocarbon, it reacts in the same manner as other organic compounds of this type. When heated to high temperatures, in the absence of air, the molecule breaks down to yield gases, organic compounds of lower molecular weight and a relatively non-volatile carbonaceous residue (coke).

Products of Coal Carbonization—Although the oxides of iron may be reduced to metallic iron by many agents, carbon (directly or indirectly) is the reducing agent found to be best suited for the economical production of iron. Carbon of suitable reactivity and physical strength was at one time produced from wood by distillation, yielding wood charcoal; but for operation of a modern large blast-furnace the carbon required for the smelting of iron is obtained from the destructive distillation of selected coking coals at 1650° F to 2000° F. Such distillation of coal (carbonization) in the absence of air results in the evolution of gases and vapors, leaving a coke residue in the oven.

The reactions occurring during the carbonization of coal for the production of metallurgical coke are complex. The process can be considered as taking place in three steps: (a) Primary breakdown of coal at temperatures below 1296° F (700° C), yields decomposition products some of which are water, oxides of carbon, hydrogen sulphide, hydroaromatic compounds, paraffins, olefins, phenolic, and nitrogen-containing compounds. (b) Secondary thermal reactions among these liberated primary products as they pass through hot coke, along hot oven walls and through highly-heated free space in the oven involve both synthesis and degradation. A large evolution of hydrogen and the formation of aro-

matic hydrocarbons and methane occur in the stage above 1296° F (700° C). Decomposition of the complex nitrogen-containing compounds produces ammonia, hydrogen cyanide, pyridine bases and nitrogen. (c) Progressive removal of hydrogen from the residue in the oven produces hard coke.

During carbonization, about twenty to thirty per cent by weight of the initial charge of coal is evolved as mixed gases and vapors which pass from the ovens into the collecting mains and are processed through the coal-chemical recovery section of the coke plant to produce coal chemicals. When the production of coke is accomplished in modern by-product coke ovens with equipment for recovering the coal chemicals, one net ton of coking coal in typical American practice yields about the following proportions of the several coal chemicals and coke, depending upon the type of coal carbonized, carbonization temperature and method of coal-chemical recovery:

Blast-Furnace Coke	1,200-1,400 lb.
Coke Breeze	100-200 lb.
Coke-Oven Gas	9,500-11,500 cu. ft.
Tar	8-12 gal.
Ammonium Sulphate	20-28 lb.
Ammonia Liquor	15-35 gal.
Light Oil	2.5-4 gal.

The coke-oven gas contains the fixed gases so classified because they are gases at 760 mm. pressure and 60° F (15.5° C). They are hydrogen, H₂; methane, CH₄; ethane, C₂H₆; carbon monoxide, CO; carbon dioxide, CO₂; illuminants which are essentially unsaturated hydrocarbons, such as ethylene, C₂H₄; propylene, C₃H₆; butylene, C₄H₈; and acetylene, C₂H₂. Other compounds present are hydrogen sulphide, H₂S; ammonia, NH₃; oxygen, O₂; and nitrogen, N₂.

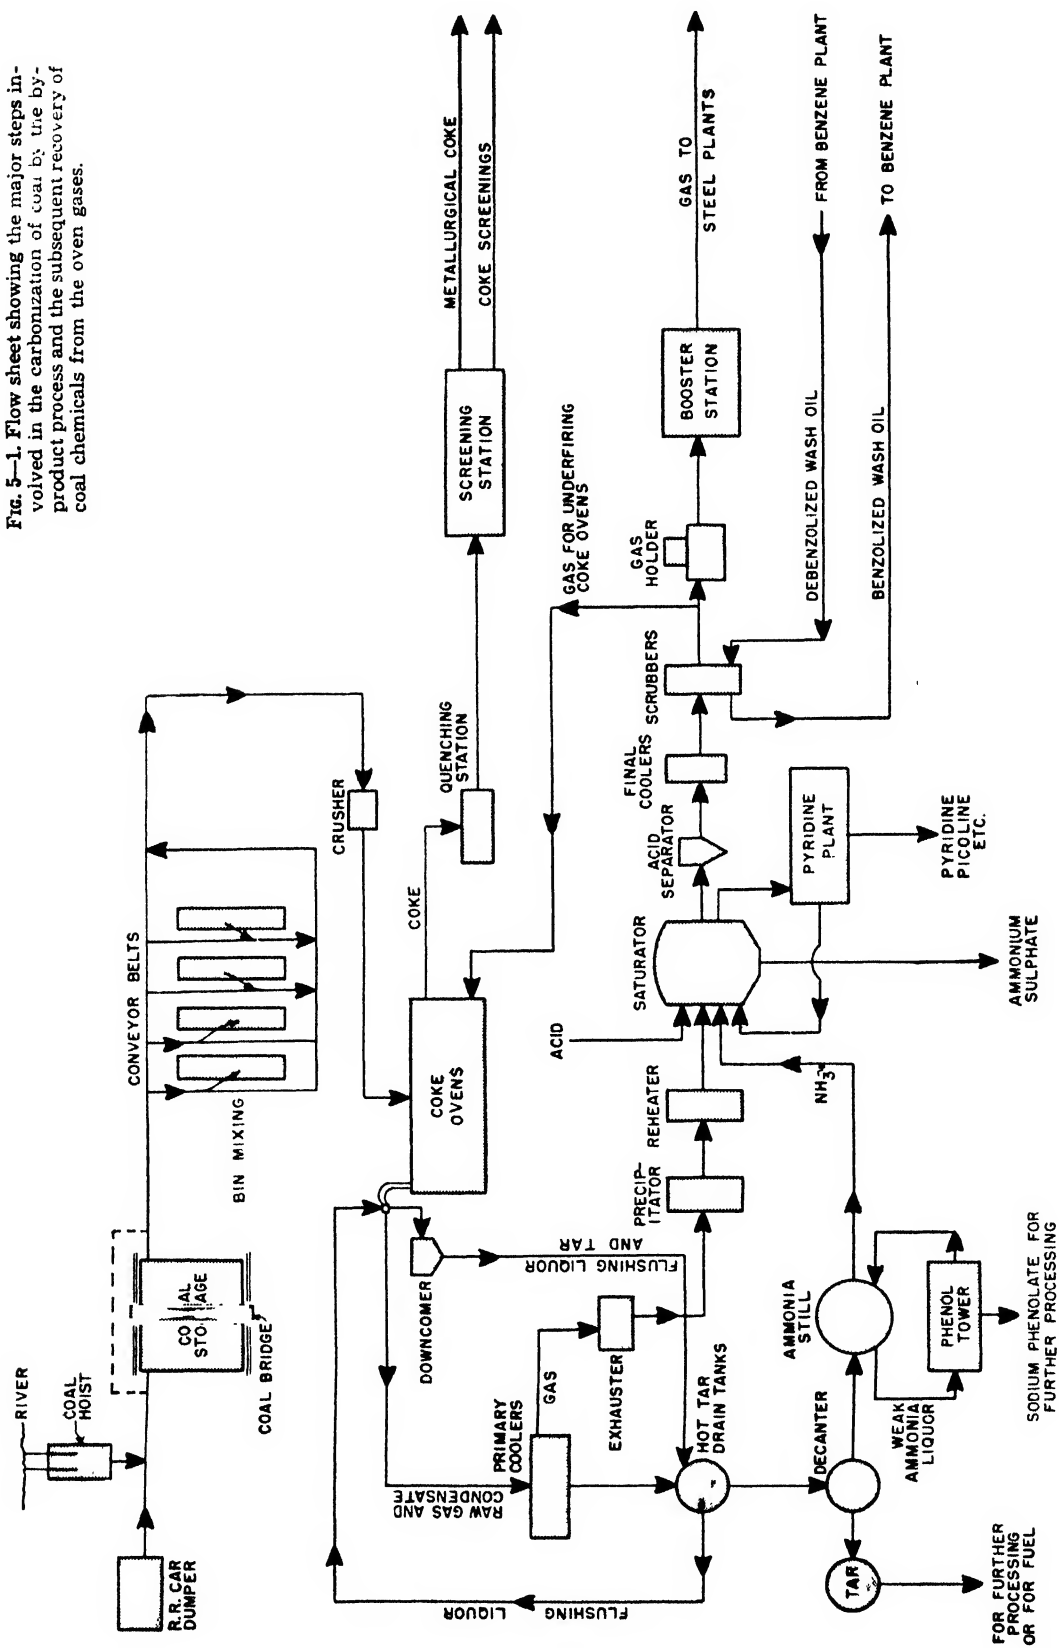

Other substances in the raw gases and vapors leaving the ovens, which are liquids at ordinary temperatures, are:

(a) **Ammonia Liquor** (primarily the water condensing from the gas), which is an aqueous solution of ammonium salts of which there are two kinds—free and fixed. The free salts are those which are decomposed on boiling to liberate ammonia. The fixed salts are those which require boiling with an alkali such as lime to liberate the ammonia.

(b) **Tar**, which is the organic matter separating by condensation from the gas in the collector mains. It is a black, viscous liquid, a little heavier than water. From it the following general classes of compounds may be recovered: pyridine, tar acids, naphthalene, creosote oil and pitch.

(c) **Light Oil**, which is a clear yellow-brown oil with a specific gravity of about 0.880. It contains varying

FIG. 5-1. Flow sheet showing the major steps involved in the carbonization of coal by the by-product process and the subsequent recovery of coal chemicals from the oven gases.

amounts of coal-gas products with boiling points from about 40° C to 200° C and from which benzene, toluene, xylene and solvent naphthas are recovered.

In the recovery of coal chemicals (Figure 5—1), the first step is the recovery of the basic crude materials

(coke-oven gas, ammonia liquor, tar and light oil) as a primary operation in accordance with commercial practice. Secondary operations consist of the processing of these primary products to separate them into their components.

SECTION 2

COLLECTION OF VOLATILE PRODUCTS FROM OVENS

Collecting Main and Suction Main—In the collection system for the recovery of the volatile products from coal, the first operation reduces the temperature of these products generally referred to as foul gas. This takes place in a system of gas mains through which the foul gas passes.

The foul gas passes out of the oven chamber through a refractory-lined ascension pipe and into a gooseneck which connects into the collecting main through a damper valve. The collecting main serves an entire battery of ovens, running parallel with the battery and extending above it on one side or on both sides depending on whether it is a single or double collecting-main operation.

The gas and vapors ordinarily leave the oven at temperatures in the range 1100–1300° F (600–700° C), and are shock-cooled by spraying with flushing liquor in the goosenecks and further cooled by spraying again with flushing liquor at different points along the collecting main. The temperature of the gas and vapors at the point of exit from the collecting main is 295 to 420° F (145 to 215° C). The cooling is effected by the evaporation of a portion of the water from the flushing liquor which removes some of the sensible heat from the gas and condenses some of the vapors with the resultant condensation of the heavy tar.

The gas and remaining vapors pass from the collecting main through one or more cross-over mains into the suction main. A pressure-regulating valve, automatically controlled, is located in each cross-over main. After the gas and vapors have passed this control valve their temperature drops to 175 to 212° F (80 to 100° C), as a result of atmospheric cooling and further evaporation of the flushing liquor.

The flushing liquor, used for cooling in the spray system, is liquor which has been condensed in the mains, collected and recirculated, amounting to 800 to 1,000 gallons per ton of coal carbonized. The flushing liquor, which cools and condenses various vapors in the gas, provides a carrying medium for the condensable tars and other compounds formed in the operations. These liquid materials flow from the collecting main through a seal into a downcomer and are delivered through the return flushing liquor lines to a collecting unit customarily called a hot tar drain tank (Figures 5—1 and 5—2), described in Section 3.

The uniform flow of gas and vapors into the system is accomplished by the charging of coal into the ovens at regularly prescribed intervals and the withdrawal of the evolved gases at a constant rate. This constant rate of removal of the gas is controlled by the automatic pressure regulator in the cross-over main. This pressure regulator provides a slight pressure of about one millimeter of water at the base of the oven prior to pushing. This control of pressure is for the purpose of eliminating the infiltration of atmospheric air or gases from the heating system into the oven, which would have a deleterious effect on the quality and quantity of the coke and coal chemicals.

As a consequence of this practice the pressure on the collecting main is about eight to twelve millimeters of water with a variable suction of about two to three hundred millimeters of water in the cross-over main after the regulating valve.

These pressure differentials are maintained by the use of either low speed positive turbo or centrifugal type exhausters designed to remove the gases and vapors at a controlled rate.

SECTION 3

RECOVERY OF CRUDE COAL TAR

Hot Tar Drain Tank—The hot tar drain tank (Figure 5—2) serves a two-fold purpose in the processing of the liquid condensates and recirculating liquor in the primary liquid system:

(a) To provide a settling basin in which the velocity of the tar and liquor is reduced to permit separation of the tar and liquor by the difference in specific gravity.

(b) To serve as the first settling point for carbonaceous and other finely divided material that is carried along with the tar and liquor from the collecting main.

There are several designs of hot tar drain tanks, but in general they consist of a rectangular tank divided into several compartments. In the first compartment the tar and liquor overflows a baffle into the main compartment. At this point an appreciable quantity of the carbonaceous sludges is collected as a residue. The tar and liquor pass into the main settling compartment where they separate into two layers. The tar settles to the bottom, due to its higher specific gravity, and flows

through a decanter pipe due to a hydrostatic head that is controlled by the level of the total liquid in the tank. The rate of tar removal is regulated by an adjustable weir located in the top of the decanter. The tar flows by gravity to a tar compartment of the hot drain tank, from which it is pumped periodically to tar-storage tanks.

Normally the tar recovered from the hot tar drain tank contains 2 to 5 per cent water. When the water content of the tar is in excess of 5 per cent further decantation or centrifugalization may be required to separate the water from the tar. If further separation between the tar and liquor is required and can be obtained by gravity separation, a tar separator tank or decanter is placed in the process lineup prior to the tar and liquor storage tanks. The mixture of tar and liquor is pumped from the tar compartment of the hot drain tank to approximately the middle section of the separating tank. Here the same process takes place as described for the separation of tar and liquor in the

FIG. 5-2. Schematic representation of a flushing-liquor decanter tank or hot tar drain tank.

settling compartment of the hot drain tank. The tar flows from the bottom of the tank through a decanter pipe by hydrostatic head (controlled by the level in the tank) to a tar-storage tank, while the liquor overflows a fixed weir plate into a liquor-storage tank. The overflow liquor from the weir plate provides flushing liquor for the sprays in the goosenecks (damper sprays) and in the collecting mains on the ovens. All of the liquor in excess of the flushing requirements is pumped to storage tanks and further processed for the recovery of ammonia and phenol. It is necessary to take a hot drain tank out of service periodically for cleaning, as the accumulation of finely divided carbonaceous sludges reduces the capacity of these facilities for separation of tar and liquor.

The more recent developments in the design and construction of hot tar drain tanks have incorporated a rotating drag scraper for the continuous removal of the accumulation of solids from the settling compartment. This eliminates a protracted out-of-service period for cleaning this equipment.

Primary Cooler—The non-condensed gas and vapors leaving the collecting and suction mains at a temperature of 167-176° F (75-80° C) require further cooling to 95° F (35° C) to remove additional tar and a major portion of the water vapor and to reduce both the volume and temperature of the gas before its admission to the exhausters. This cooling may be conducted in either direct or indirect primary coolers.

The **direct primary cooler** (Figure 5-3) consists of a tall, cylindrical scrubbing tower fitted with hurdles or baffles usually constructed of wood. The top portion is equipped with a series of spray nozzles and the lower portion contains a chamber to collect the liquor and condensate which flows by gravity into the hot drain tank.

The gas enters the bottom of the tower and the cooling liquor is pumped into the top of the tower through the spray system to provide a downward flow of cooling liquor in counter-current flow to the gas stream. This direct contact between the gas and liquor provides for exchange of heat which is transferred from the hot gas to the cold liquor. This heat is removed from the liquor by indirect heat exchange, through tubular heat exchangers, with circulating water. As a result of this cooling, 20 to 25 per cent of the total tar recovered is condensed along with a considerable quantity of weak liquor containing ammonia. These condensates are

processed through the hot tar drain tanks either separately or in conjunction with the tar and liquor condensates from the collecting main.

The **indirect primary cooler** used for cooling the gas is a heat exchanger, in which water is used for cooling by heat exchange through steel tubes. The water flows through the tubes and the gases pass around the tubes.

Tar Extractor—The gas leaving the primary coolers still contains small amounts of tar that would cause difficulty in the operation of subsequent units in the recovery system. There are two methods available for removal of this entrained tar: (a) mechanical impingement and (b) electrostatic precipitation. In the case of operation by mechanical impingement, it is necessary to place the equipment after the exhausters, but the electrostatic precipitator may be placed before or after the exhausters. The preferred location is after com-

FIG. 5-3. Schematic diagram of a direct primary cooler. (Courtesy, Koppers Company, Inc.)

Fig. 5-4. Diagrammatic representation of an electrostatic precipitator for precipitation of tar from raw coke-oven gases. (Courtesy, Koppers Company, Inc.)

pression to avoid any infiltration of air into the unit. The electrostatic type represents the modern concept of removing tar from gas.

The mechanical-impingement type of tar extractor was developed by Pelouze and Audouin, and is commonly referred to as the P & A tar extractor. The principle of operation is based on the fact that when gas containing suspended solids is impinged (at high velocity) on a solid surface, deposition of the suspended particles takes place. This principle is made effective by forcing the gas through restricted spaces directly against a plate to develop a dispersion of the mass and effect a deposition of tar particles, which coalesce to form a liquid and flow to the bottom of the separator. The fixed gas then continues on through this unit for subsequent processing operations. The gas enters the tar extractor through a pipe connected near the bottom and passes through seven standpipes over each of which a series of three concentric perforated shells is suspended. Each assembly of three shells is called a bell. The ascending gas enters the inside of each bell and passes through the perforations, impinging on the solid

face of each succeeding shell to deposit the tar, and finally passes out of the top of the extractor.

The operation of this type of extractor requires the maintenance of a constant differential pressure of eight to ten inches of water, regulated by the liquor seal.

The electrostatic precipitator has been found to be more efficient and is gradually replacing the mechanical impingement type of tar extractor. In the electrostatic precipitator (Figure 5-4) removal of tar fog from gas is achieved by passing the gas through two electrodes having a high electrical potential. The discharge electrode is of small cross section, such as a wire or a series of points, in order to develop the high-intensity electrical field at its surface which is required for ionization of the gas. The collecting electrode has a large cross section and serves as a collector for the suspended particles which are ionized and transferred to this electrode. In this operation, the electrostatic precipitator, in addition to its function as a collecting unit for dispersoids, also serves to catalyze the formation of vapor-phase gums formed by oxides of nitrogen and unsaturated hydrocarbons.

SECTION 4

RECOVERY OF AMMONIA AS AMMONIUM SULPHATE

Ammonium sulphate is formed by the reaction between ammonia and sulphuric acid. The dry chemically pure salt is white in color and contains 25.78 per cent of ammonia. The commercial salt varies in color from white to grayish tan and contains from 25.0 to 25.7 per cent of ammonia.

The ammonia formed during coking exists in both the water and gas that form part of the volatile products. The recovery of this ammonia can be accomplished by three different methods: (a) the direct process in which the total vapor, after separation of condensed tar, is passed through a saturator containing a solution of sulphuric acid to absorb the ammonia; (b) the indirect process in which the ammonia is removed from the gas by scrubbing with water and then removed from the water by distillation and treatment with an alkali, after which the ammonia and steam are passed through the saturator and (c) the semi-direct process in which the ammonia in the liquor produced during carbonization is removed by distillation and alkali treatment and added to the gas stream, the gas containing all of the ammonia being then passed through an absorber con-

taining dilute sulphuric acid for the extraction of ammonia.

Semi-Direct Process—Of these three processes, the semi-direct is most extensively used at the present time and will, therefore, be discussed in detail. The ammonia present in the weak liquor is in two forms classified as "free" and "fixed". The free ammonia is that which is readily dissociated by heat, such as the ammonium carbonates, sulphide, cyanide, etc., while the fixed ammonia is that which requires the presence of a strong alkali to effect displacement of the ammonia from the compound in which it is present, such as ammonium chloride, thiocyanate, ferrocyanide, sulphate, etc. The operation to recover this ammonia is carried out in an ammonia still.

Ammonia Still—In the processing of the liquor, a constant-head tank supplies a uniform flow of liquor, by gravity, to the top of the "free leg" of the ammonia still (Figure 5-5) and this liquor passes down the column over a series of plates equipped with bubble caps and overflow pipes. This liquor is heated by an upward flow of steam which vaporizes the ammonia

sprayed again with a more concentrated solution of sulphuric acid. The gas leaving the pyridine scrubbers is passed through the acid separator where entrained liquids are removed, after which the gas enters the final cooler.

As the dilute sulphuric acid sprays the gas rising through the ammonia absorber, the ammonia in the gas combines with the acid to form ammonium sulphate. The resulting solution drains to a crystallizer from which it is recirculated to the absorber. A constant flow of sulphuric acid is added to the ammonia absorber to replace the acid neutralized by the ammonia in the coke-oven gas. After the solution becomes super-saturated, crystals of ammonium sulphate are precipitated in the crystallizer and accumulate as a slurry in the bottom. A portion of this slurry is removed from the crystallizer and is pumped to the slurry tank where the salt settles, the liquid overflows and returns to the ammonia absorber. The concentrated slurry is withdrawn from the bottom of the slurry tank and is fed in batches to the centrifugal dryers. These dryers currently are arranged to perform the following sequence of operations automatically: (a) rinse the dryer-basket screen with water; (b) feed the slurry into the basket; (c) neutralize the acid remaining in the salt with a dilute solution of aqueous ammonia; (d) rinse the salt with water to remove excess ammonia; (e) centrifuge the water from the salt in the basket; (f) remove the dried salt from the basket; and (g) discharge it onto a conveyor belt. The liquid portion of the slurry is recovered and returned to the ammonia absorbers. The partially-dried ammonium sulphate is conveyed to heated rotary-drum dryers for final drying to a content of approximately 0.1 per cent water.

Following the ammonia removal in the ammonia

absorber, the gas comes in contact with more concentrated sulphuric acid in the pyridine scrubber which removes the tar bases (pyridines, picolines, etc.). Tar bases and sulphuric acid form a weak bond, therefore, the bases are the last to be removed from the gas and the first to be released at low acid concentrations. The tar-base sulphuric acid solution is continuously recirculated and systematically portions are removed for recovery of the tar bases by methods described in Section 6. The pyridine-free liquor is returned to the ammonia absorbers. The gas entrains some of the acid solution in the pyridine scrubber, which is recovered by centrifugal force as it passes through the acid separator.

Another process for the recovery of ammonia is the Wilputte low-differential controlled-crystallization process for producing ammonium sulphate, the equipment for which is constructed of stainless steel throughout (Figure 5-7). In this process the gas is passed through a spray-type absorber over which is circulated a 6 per cent solution of sulphuric acid nearly saturated with ammonium sulphate. The acid entrainment arrestor is an integral part of the absorber. Leaving the absorber, the solution is delivered to the solution-circulating system of a crystallizer in which crystallization takes place by the combined cooling and concentration effects of vacuum evaporation. By the variation of circulating rate and the degree of concentration, the size range of the product can be controlled closely within narrow limits. As the crystals grow in size, they settle or gravitate to the bottom of the suspension tank from which they are delivered to a slurry feed tank and from there to a continuous centrifuge. The accumulation of deposits of hard salt within the equipment is minimized and "killing" for removal of such deposits is very infrequent. The product is dust-free, neutral, free flowing

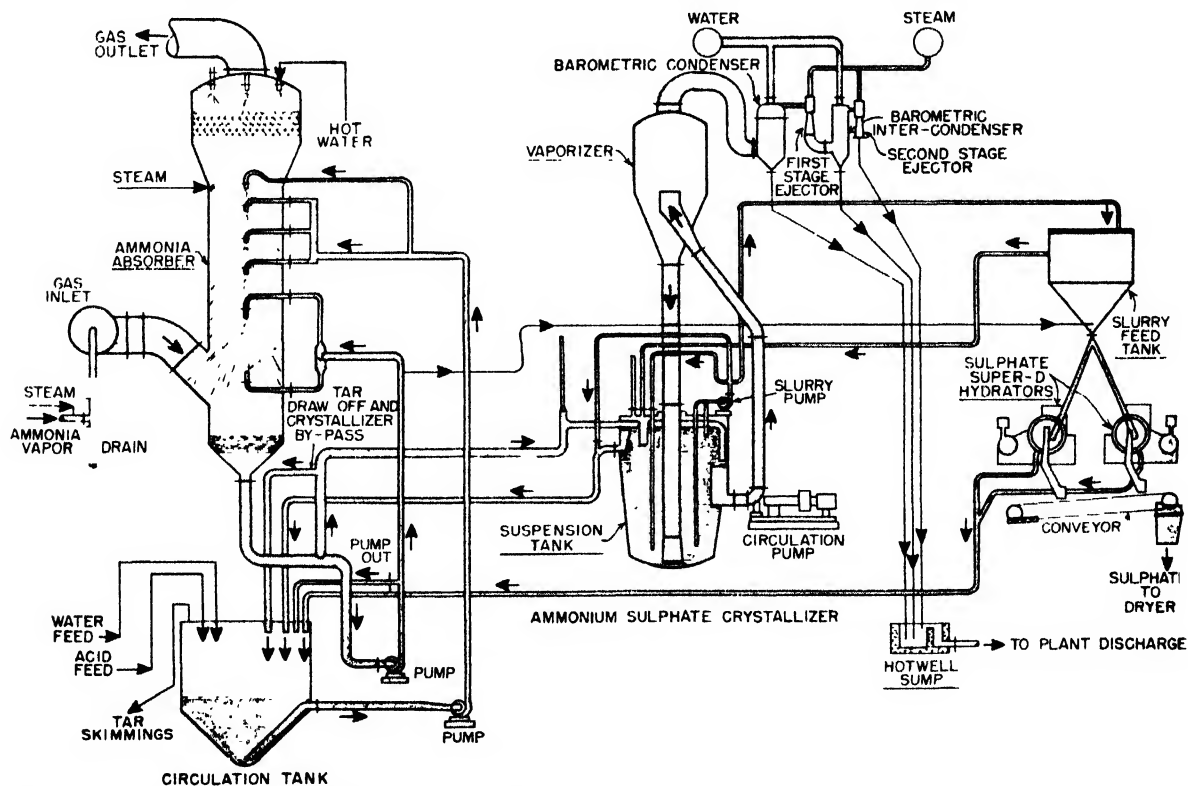

FIG. 5-7. Flow sheet of the Wilputte low-differential controlled-crystallization process for producing ammonium sulphate.

and non-caking and can be made with a size consist favorable to any type of application.

Saturator—At coke plants built prior to about 1930, ammonia-absorbing facilities consist largely of a device often referred to as saturators. These facilities are large dome-shaped, cast iron, lead-lined vessels, sometimes operated in pairs. Gas is admitted to the saturator through a distributor called a "cracker pipe" which, in the older designs, runs completely around the inside circumference of the unit and has a cross section in the shape of an inverted U. The bottom of the pipe is open, but the gas is discharged from it through numerous vertical slots, located on each side of the pipe near the bottom. This arrangement was adopted to provide a large surface for direct contact between the ammonia and dilute acid, which reacts according to the following to form ammonium sulphate:

The salt precipitates and settles to the bottom of the unit when the saturator bath becomes super-saturated. The salt is either siphoned through ejectors to elevated drain tables by means of compressed air, or removed from the base of the saturator by centrifugal pump. When the saturators are equipped with air ejectors, the salt is removed periodically from the elevated drain tables, placed in a pendulum-type centrifugal dryer,

and centrifuged for about 5 minutes, which process removes nearly all the mother liquor. The ammonium sulphate is washed with hot water, to free the crystals of absorbed mother liquor, and whizzed for about 10–12 minutes longer. It is then removed from the centrifugal basket by an unloader or plow and delivered to a belt conveyor, which carries it to a salt pit where any free acid is neutralized by spraying with concentrated ammonia liquid. The mother liquor derived from this operation, as well as the wash water, flows back into the saturators. The acid concentration of the bath is held approximately constant by adding periodically high-strength sulphuric acid.

Continued use of a saturator results in the accumulation of salt within the saturator, which interferes with the flow of gas. It is common practice to prevent such accumulations and to dissolve accumulated salt deposits by "killing" the bath periodically. "Killing" the bath is a term used to describe the method for rectifying this condition, whereby the height and acidity of a bath, prior to "killing", are allowed to decrease and the deficiency then made up by the addition of a definite quantity of acid, water, and mother liquor. The bath then has a free sulphuric acid concentration of 12–14 per cent. These added materials reduce the saturation of ammonium sulphate in the total liquor and all deposits of salt are redissolved.

SECTION 5

RECOVERY OF PHENOL

The water, i.e., weak ammonia liquor, recovered with the volatile products of coal carbonization contains 0.5 to 3.0 grams per liter of phenol (sometimes called carbolic acid) and its homologues. In order to recover this phenol, two processes are available—the vapor-recirculation process and the solvent extraction process. (Phenol is also recovered from coal tar, by processes described in Section 9 of this chapter.)

Vapor-Recirculation Process—This process utilizes the vapor pressure of phenol and operates in conjunction with the ammonia still. The weak liquor first is distilled in the free leg of the ammonia still in order to remove the maximum quantities of the acidic gases, H_2S , CO_2 , and HCN , but the minimum amount of phenol. In order to make this separation, improvement in the rectifying efficiency of the free leg by addition of a section packed with Raschig rings has been necessary.

The quantity of steam to the free leg is also reduced so that the vapors leave the top of the free leg at about 203°F (95°C), instead of at about 220°F (104°C) which otherwise would be their temperature. This

FIG. 5—8. Schematic representation of the steps in the vapor-recirculation process for the recovery of phenol from ammonia liquor. Side of column has been partially cut away to show spray arrangement. (Courtesy, Koppers Company, Inc.)

quantity of steam is sufficient to remove ammonia and the acidic gases satisfactorily without an excessive loss of phenol. This method of operation has resulted in diminishing the phenol loss to an average of 5 per cent compared with 20–30 per cent in the absence of this control.

The ammonia liquor leaving the base of the "free leg" is then transferred to the dephenolizing unit, where the phenols are removed. The dephenolized liquor is returned to the "lime leg".

In the operation of the dephenolizing unit (Figure 5–8), the liquor is pumped into the top of a dephenolizing tower consisting of two main sections. In the upper section it passes downward over wooden hurdles and meets a countercurrent flow of steam which vaporizes the phenols. The liquor from the base of the upper section returns to the ammonia still. The phenol vapors and steam are carried into the bottom of the tower and travel upward through steel turnings where they meet a countercurrent flow of caustic soda which extracts the phenols and forms sodium phenolate.

This operation is conducted at 212° F (100° C). At this temperature, the equilibrium of the phenol-sodium phenolate reaction is such that a suitable balance between the utilization of sodium hydroxide and the loss

of phenol results in the conversion of about 50 per cent of the available sodium hydroxide into sodium phenolate with a loss of about 5 per cent of the phenol.

Solvent Extraction Process—This method is based on the principle that the phenols are more soluble in benzene or light oil than in water and that the phenols can be extracted from benzene or light oil with caustic soda.

The process consists of treating weak liquor containing phenols with benzene or light oil in two or three stages by countercurrent flow. In the first stage of contact, the weak liquor from which the major part of the phenol has been extracted is treated with benzene or light oil from which the phenols have been removed. The solvent is then contacted with liquor that is richer in phenol. This operation may be carried to a third contact zone in order to increase the phenol content of the solvent.

The solvent is removed from the liquor system and treated with caustic soda in two or three steps in order to remove the phenol from the solvent and recover the phenol as sodium phenolate. The sodium phenolate is then boiled to remove the entrained solvent. It is then neutralized with sulphuric acid or carbon dioxide gas to liberate the crude phenol.

SECTION 6

RECOVERY AND REFINING OF PYRIDINE BASES

Among the products of carbonization of coal are the pyridine bases. Part of these bases dissolve in the tar, while the remainder is present in the gas going to the saturators. The pyridine bases include pyridine, picolines (methyl pyridines), lutidines (dimethyl pyridines), etc. These compounds being basic in nature dissolve in the saturator liquor with the formation of pyridine sulphate. Where pyridine recovery operations are practical, the acidity of the saturator liquors must be carefully controlled. Two processes for the recovery

of these bases from saturator liquors are described in the following. Recovery of pyridine bases from tar is described in Section 9 of this chapter, dealing with the refining of coal tar.

Saturator liquor is withdrawn continuously from the feed tank to the continuous dryers at a predetermined rate and conducted to a neutralizing still, where the neutralization of the saturator liquor and separation of the bases from the neutralized liquor are effected simultaneously. Ammonia vapors (containing carbon

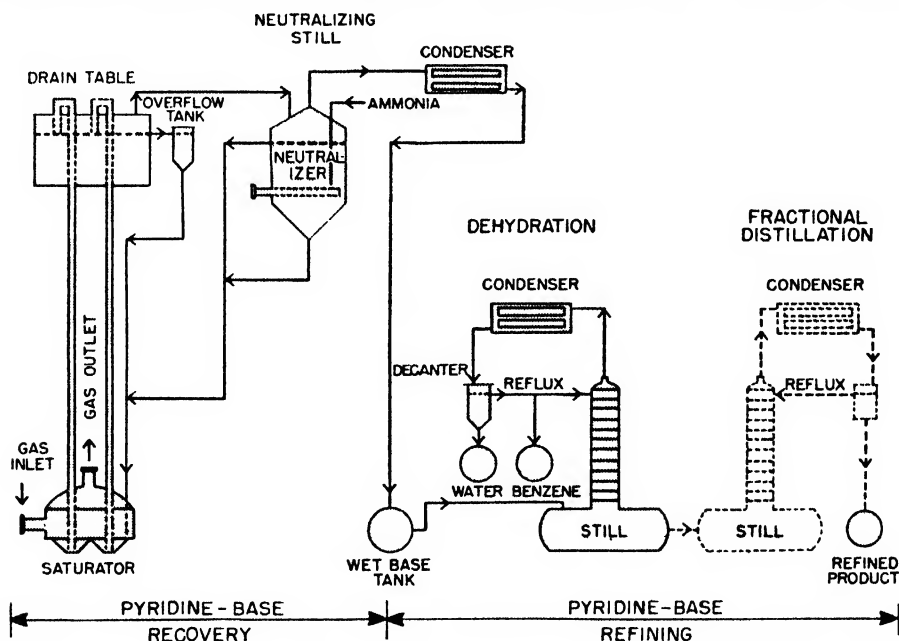

FIG. 5–9. Flow sheet of a batch-type plant for recovery and refining of pyridine bases. The equipment at the far right is shown dotted because the same still is used for both dehydration and fractional distillation, except that, in the latter case, the decanter is not employed.

dioxide) are taken directly from the fixed leg of the ammonia stills, and conducted into the neutralizing still at a constant rate.

The neutralizing still is fitted with a dephlegmator which operates with a top vapor temperature of from 185 to 195° F (85 to 90° C). Pyridine bases, ammonia, carbon dioxide, and water, distill overhead and are conducted to the separating unit, while the ammonium sulphate liquor is withdrawn continuously from the bottom of the still and returned to the saturator.

The vapors from the dephlegmator pass downward through a condenser and the condensate therefrom is conducted below the level of liquid in the separator. The ammonia, carbon dioxide, and water unite to form a solution of ammonium carbonate with a specific gravity of 1.07 to 1.08. The pyridine bases separate from this ammonium carbonate solution as a top liquid layer containing about 15 per cent water and are decanted continuously into a receiving tank. The ammonium carbonate solution is maintained at a constant level by withdrawing through a constant level device and returned to the neutralizing still. This is done in order to maintain an equilibrium of ammonia and carbon dioxide in the system which results in a solution of the desired specific gravity in the separator.

In another method of continuous operation, the pyridine bases are completely condensed at the time of neutralization and separated from the saturator liquor by gravity.

Batch-Type Recovery Process for Pyridine Bases—Pyridine bases may be recovered by the intermittent removal of saturator liquor from the saturator and batch treatment of this liquor for the recovery of the pyridine bases (Figure 5—9).

The recovery equipment consists of a lead-lined tank which serves as a receiving tank and still. Its capacity

is designed to hold the saturator liquors that will be removed from all saturators in 24 hours. It is equipped with a steam coil and an open pipe for the ammonia feed. A condenser is provided to condense the water and pyridine bases distilled over and a receiving tank for the wet product.

In the daily operation for the recovery of the bases 250–300 gallons of saturator liquor are removed from each saturator twice per 24 hours. The liquor is removed from the drain table and delivered to the mother liquor wells. This liquor, containing from 25 to 40 grams per liter of pyridine bases and 80 to 100 grams per liter of free acid, is transferred to the neutralizing still where it is treated with ammonia until the bases are liberated; this operation is called "springing". The liquor in this still is then heated and the bases are distilled off and condensed as a water solution containing 40 per cent of bases.

Refining of Pyridine Bases—The crude pyridine bases are first dehydrated by azeotropic distillation, using benzol as the entrainer.

The wet pyridine bases are charged to a still with a quantity of benzene. The quantity of benzene should be sufficient to form the azeotrope with water during distillation. The distillation is controlled by maintaining the vapor temperature at 157.1° F (69.5° C) until the water has been removed. The benzene and water are separated in a decanter tank where the water is sent to the waste disposal system and the benzene returned to the still.

After the water has been completely removed, the still is adjusted to provide a balance between the forward flow and reflux return to separate the benzene from the pyridine and then continued for the recovery of refined pyridine, picolines, and higher boiling point bases.

SECTION 7

RECOVERY OF COKE-OVEN LIGHT OIL

Light Oil—The gas leaving the saturators contains light oil. This oil is a clear yellow-brown oil with a specific gravity of about 0.880. It is a mixture of all those condensable products of coal gas with boiling points up to 390° F (200° C), containing well over a hundred constituents (Table 5—I). Most of these are present in such low concentrations that their recovery is seldom practicable. Many of the constituents, such as, olefin and diolefin hydrocarbons, some straight chain and cyclic paraffins and small amounts of sulphur, nitrogen and oxygen compounds, are present in small quantities, while those few present in larger quantities constitute the products which are economically recoverable. The principal usable constituents are benzene (60–85 per cent), toluene (6–17 per cent), xylene (1–7 per cent), and solvent naphtha (0.5–3 per cent). Light oil constitutes approximately one per cent of the coal carbonized.

Light-Oil Recovery Process—The removal of light oil from coal gas is generally the last step in the coal chemical recovery process.

There are three general methods used for the recovery of light oil:

(a) Refrigeration and compression involving temperatures below -70° C and pressures of 10 atmospheres.

(b) Adsorption by solid adsorbents involving the removal of light oil from the gas by passing it through a bed of activated carbon and recovering the light oil from the carbon by heating with direct or indirect steam.

(c) Absorption by solvents involving washing the coal gas with a petroleum wash oil or other absorbents followed by steam distillation of the enriched wash oil to recover the light oil.

The latter practice (Figure 5—10) is the one almost universally followed in the United States, due to the availability and low cost of petroleum wash oil, and is the method that will be discussed here. The efficiency of recovery varies widely with the seasons since one of the major considerations is the temperature of the coal gas and wash oil entering the absorbing process. Another consideration is the ratio of wash oil to gas. The absorption equipment should be of reasonable design as to size and contact time. The oil-and-gas ratio varies depending on the equipment design and light-oil content of the gas prior to light-oil removal.

Typical operating conditions are as follows: the temperature of gas entering the absorption process is 59–86° F (15–30° C), the temperature of wash oil entering the process is 60–90° F (17–32° C) and the wash oil circulated per ton of coal carbonized is 150–200 gallons.

The boiling point of the wash oil should be well above 390° F (200° C) so as to permit an effective separation of light oil from wash oil in debenzolization. The oil should not thicken and should have a low viscosity to permit its distribution in the scrubbing towers. It should not deteriorate readily but maintain its initial properties as long as possible to keep makeup oil at a

minimum. It must be especially stable with respect to the repeated heating which takes place in the recycling of the oil in the process. Its absorptive capacity should be very high and it should not react with or contaminate the coal gas. The specific gravity should be low enough to permit effective separation of wash oil and water in the processing and keep emulsification of the two to a minimum. The specific heat should be low because the oil is subjected to repeated heating and cooling as it is recycled in the process.

The petroleum wash oil normally used for this absorption process has a boiling range of 518-622° F (270-350° C). Other specifications which are general for a petroleum oil include a specific gravity of about 0.830, a viscosity of 45 seconds Saybolt at 100° F (38° C), a pour point of 35° F (2° C), an emulsification of 95 per cent separation in 50 seconds, a flash point of 300° F (150° C), fire point of 335° F (168° C), and a low residue under 0.10 per cent when heated for a period of five days at approximately 300° F (150° C).

Final Cooler—The first step in the recovery of light oil by absorption in a liquid medium is that of cooling the gas leaving the saturators at a temperature of 112-140° F (50-60° C) by direct contact with water in a tower scrubber called a final cooler. The facilities are so named since the gas is here given its final cooling in the coal-chemical processing. This is necessary to remove naphthalene from the gas and also cool the gas prior to its admission to the wash-oil scrubbers.

The tower consists of a tall cylindrical shell of steel approximately 10 to 15 feet in diameter and 50 to 75 feet in height filled with a suitable packing material, either metallic or wooden. The gas enters near the bottom of the tower and passes up through the packing material and out near the top. The cooling water enters the top of the tower through a spray system and

the water passes down through the tower, coming in direct contact with the gas in a countercurrent manner. The water leaves the tower at the bottom through a sealed outlet pipe to prevent escape of any gas. The heat from the gas is transferred to the water, which in turn is cooled in an induced-draft water-cooling tower with air or in an atmospheric water-spray cooling operation. Cooling of the water depends upon air circulation and the vaporization of a part of the water in circulation, the latent heat of vaporization of the water being responsible for additional cooling. Operating practice is to cool the water, and in turn cool the gas, to as low a temperature as practicable, depending upon atmospheric temperature, since most effective absorption of light oil is obtained at low temperatures. Cooling is not carried below 60° F (15° C), since below that temperature petroleum absorbing oil becomes too viscous to flow freely.

This direct-cooling operation causes the condensation of a major portion of the naphthalene and any entrained tar and vapor-phase gums. The naphthalene is recovered in a sump operation and is either added to the tar or refined directly to provide a salable product.

In some of the more modern facilities, the lower part of the final-cooler tower is redesigned to permit the outlet water to come in direct contact with tar in order to dissolve the naphthalene as it is being removed from the gas.

Wash-Oil Scrubber—The second step in the recovery of light oil is its absorption in the liquid petroleum wash oil. The gas comes in direct contact with the wash oil in one or more tall scrubbing towers containing packing. The gas passes from the first tower to the last in series and the wash oil travels from the last tower to the first in reverse series. The flow of gas and wash oil is countercurrent in each tower. The steel towers are

approximately 15 to 22 feet in diameter and 100 feet in height.

The wash oil is introduced through a number of sprays in the top of the tower and comes into direct contact with the gas, which flows from the bottom to the top. An oil-storage tank is provided in the base of the tower to receive the oil and maintain a surge capacity for pumping the oil away. The oil passes from the gas compartment to oil storage through a sealed pipe. It is pumped from the base of one tower to the spray system in the top of the next tower in the series. From the last tower the oil is pumped to the stripping stills for separation of light oil from wash oil. Wash oil prior to light-oil absorption is called debenzolized and, after absorption, benzolized. The benzolized wash oil contains 2 to 3 per cent light oil. The debenzolized wash oil is cooled in indirect cast-iron or steel-pipe cooling coils with water to a temperature several degrees higher than that of the gas entering the scrubbers, which is 60 to 75° F (15 to 25° C). This is to prevent condensation of water from the gas, which would form an emulsion with the oil, causing clogging of the free space in the packing of the tower. The rate requirement for the circulation of oil through the scrubbers is a function of the vapor-pressure distribution between the light oil dissolved in the absorbent oil and that remaining in the gas at the temperature of operation. From 90 to 95 per cent of the light-oil content of the gas is recovered in this operation. The wash oil, after being cooled, passes through a large decanting tank which acts as a settling compartment for the emulsified and resinous materials present in the wash oil. This material accumulates in the bottom of the tank, and the wash oil decants off at a higher level to a small receiving tank, from which it is pumped to the top of the first scrubbing tower in the series. Generally, two decanting and two receiving tanks are provided to permit cleaning the residue from the tanks periodically.

Recent designs of wash-oil scrubbers are not fitted with hurdles and packing used in the previous type. Contact between the gas and absorption oil is accomplished by the use of single conical sprays placed at three different elevations within the tower, as shown in Figure 5—11. Absorption oil pumped through the top pressure spray is collected by steel-plate umbrellas, and passed through second and third spray nozzles of the gravity-flow type. Baffles direct the flow of gas toward the spray in every pass and horizontal angles restore correct distribution above each umbrella collector. Restrictions to gas flow by accumulations of residues commonly found in packed scrubbers are minimized or eliminated in scrubbers of this design.

Debenzolization of Wash Oil—In the debenzolization step, the light oil (2 to 3 per cent) in the benzolized wash oil is separated by steam distillation. The carry-over of absorbing oil into the light oil is kept to about 5 per cent and the debenzolized absorbing oil contains 0.2 per cent light oil.

In the straight steam-distillation process at atmospheric pressure, the benzolized wash oil is preheated to approximately 212° F (100° C) with a vapor-to-oil and an oil-to-oil heat exchanger. Heating is continued to 295° F (145° C) with an indirect preheater of the shell-and-tube type with the oil flowing through the tubes using steam as the heating medium on the shell side. The preheated oil is introduced near the top into a multi-plate bubble-cap fractionating column leaving several plates above the feed to keep entrainment of wash oil to a minimum. (Figure 5—13 shows the plate and bubble-cap arrangement in a still of similar design.) The benzolized wash oil flows down the column counter-

Fig. 5—11. Schematic representation of a spray-type wash-oil scrubber.

current to upward flow of live steam, which is introduced in the base of the still column. The debenzolized wash oil leaving the base of the column through a sealed outlet at a temperature of 290 to 300° F (145 to 150° C) passes through the oil-to-oil heat exchanger in which it is cooled to 212° F (100° C) giving up its heat to the incoming benzolized wash oil. Water separates out at this point and is drained off. The wash oil passes through a pumping tank and is pumped at 212° F (100° C) to cooling coils for cooling prior to being used again as an absorbent for the light oil in the scrubber towers.

The mixture of steam and light oil vapors leaving the top of the column flows through the tubular vapor-to-oil heat exchanger which recovers heat and also acts as a partial condenser. Sufficient heat is imparted to the incoming benzolized oil to raise its temperature 45° F (25° C) and, at the same time, the vapors are cooled to cause a portion of the steam and high-boiling constituents of light oil to condense (the condensate of which carries along some of the wash oil which was carried over the top of the column as entrainment). The mixture of oil and water is separated in a gravity separator tank, the water flowing to the sump system and the oil returned to the debenzolized oil streams. The mixture of steam and light-oil vapors leaving

the vapor-to-oil heat exchanger passes to a water-cooled condenser, which is of a multi-pass design, with the vapor and water flowing countercurrent to each other. The condensate flows to a gravity separator effecting a separation of the light oil and water, the light oil flowing to storage and the water to the sump system.

In some designs, an additional fractionating column is added to the debenzolization process for rectifying the light-oil vapors from the vapor-to-oil heat exchanger. In this case, the condensate of the vapor-to-oil heat exchanger, after separation of the water, is also introduced into the rectifying column. The mixture of steam and light-oil vapors enters the multi-plate bubble-cap rectifying column near the middle section. The light oil is separated into two fractions: the distillate containing forerunnings, benzene, toluene, xylene, and low-boiling solvent; while the residual fraction contains an admixture of high-boiling solvents, naphthalene and wash oil. A portion of the distillate is returned to the top of the column as reflux, the control point being the vapor temperature at the top of the column.

In the more modern debenzolization processes, the benzolized wash oil is processed at a temperature of 195 to 250° F (90 to 120° C) and this eliminates the need for an oil-to-oil heat exchanger in the process lineup.

SECTION 8

REFINING OF COKE-OVEN LIGHT OIL

Light oil is separated into a number of marketable products by refining according to trade specifications. The aromatic hydrocarbons in crude light oil, which are present in large quantities, are the principal source of the commercial products. These hydrocarbons are ben-

zene, toluene, xylene, coumarene and indene. The remaining substances, which are present in small quantities, are generally considered to be impurities. These consist of saturated straight-chain hydrocarbons, paraffins, saturated closed-chain or cycloparaffin and naphtha-

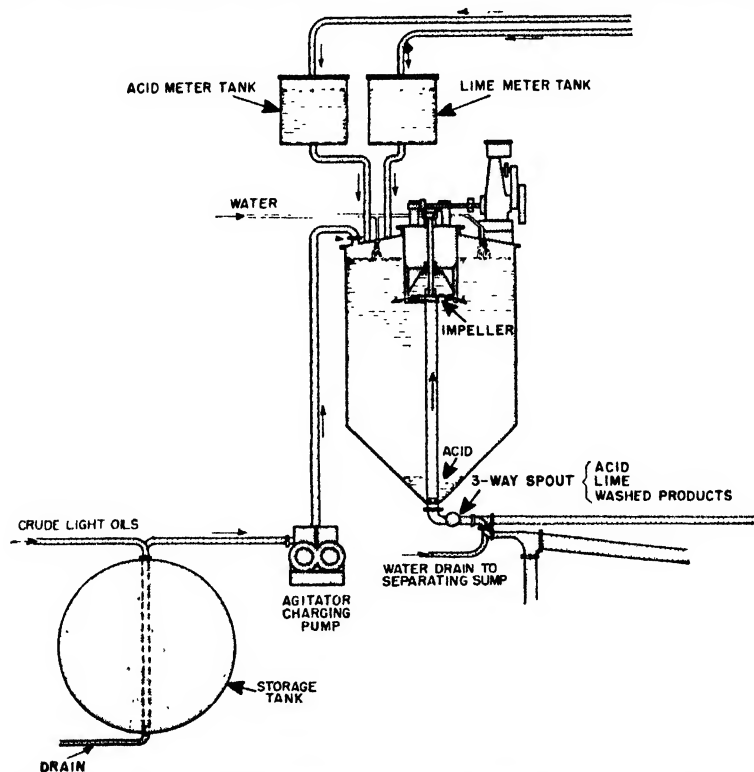

FIG. 5-12. Schematic representation of an acid washer. (Courtesy, Koppers Company, Inc.)

lene hydrocarbons, unsaturated hydrocarbon olefins and diolefins, sulphur compounds (carbon disulphide, thiophene and its homologues), nitrogen compounds (pyridine and its homologues), and oxygen compounds (phenol and its homologues).

Acid Washing—Washing light-oil fractions with sulphuric acid removes impurities by chemical reaction of the acid with the impurities (Figure 5—12). These particular impurities cannot be removed by fractional distillation. The chemical reactions involve oxidation, polymerization, sulphonation and other complex reactions with the unsaturated hydrocarbon olefins and diolefins, sulphur, nitrogen and oxygen compounds. The reaction products remain in solution in the acid and are removed with it by gravity separation from the washed oil. The acid-washed oils are, after neutralization, separated into individual constituents by fractional distillation.

Fractional Distillation—Fractional distillation separates the principal aromatic components of light oil by repeated vaporization of a mixture of these compounds (which have different boiling points) followed by condensation of the vapors in such a way that the desired degree of separation of the components is obtained.

The following proportional distribution of the main constituents in light oil, based on distillation range, indicates the relationship of quantities involved:

Fraction	Distribution	Approx. Boiling Points
Forerunnings	1.5- 2.5%	77-158° F (25-70° C)
Pure Benzene	60.0-85.0%	176.2° F (80.1° C)
Pure Toluene	6.0-17.0%	231.1° F (110.6° C)
Pure Xylenes	1.0- 7.0%	275-293° F (135-145° C)
Heavy Solvents	0.5- 3.0%	338-392° F (170-200° C)
Residues	5.0-11.5%	392° F (Above 200° C)

The particular operating sequence in regard to acid washing and distillation varies, depending on quality of

crude light oil, the equipment available, and the market demands. A complete examination is required in each plant to plan effectively the type of operation which will be most satisfactory.

The evolution of the refining practice for the processing of light oil started with its use as a motor fuel, which has been followed through the years with the gradual consumption of individual products for solvent and chemical purposes. During World War I the important use was the production of trinitrotoluene from toluene. In World War II, in addition to the use of toluene as mentioned, benzene became important for synthetic rubber and aviation fuel, xylene for protective coatings. Advances in importance of the aromatic products for commercial use in recent years has been accompanied by the improvement of refining techniques.

In the earlier distilling operations, only batch stills were used whereas modern refining techniques make use of continuous stills.

Batch Still Operation—A batch still consists of a kettle connected to a fractionating column by means of a vapor pipe to carry vapor to the column, and a liquid-sealed pipe to permit return flow of liquid to the kettle. This column contains thirty to forty plates which are fitted with bubble caps and return flow lines to permit condensate to return to each succeeding lower plate. The actual number of plates, bubble caps, etc., must be determined from design characteristics dictated by the separation to be performed on the material to be distilled. The kettle is equipped with steam coils with sufficient surface for the available steam pressure to supply the column with vapor at a predetermined rate. A vapor pipe receives the vapors from the top of the column and delivers them to a condenser which may also be equipped with an aftercooler. The condensate may then be collected in a receiving tank and a part pumped to the top of the column to provide reflux for

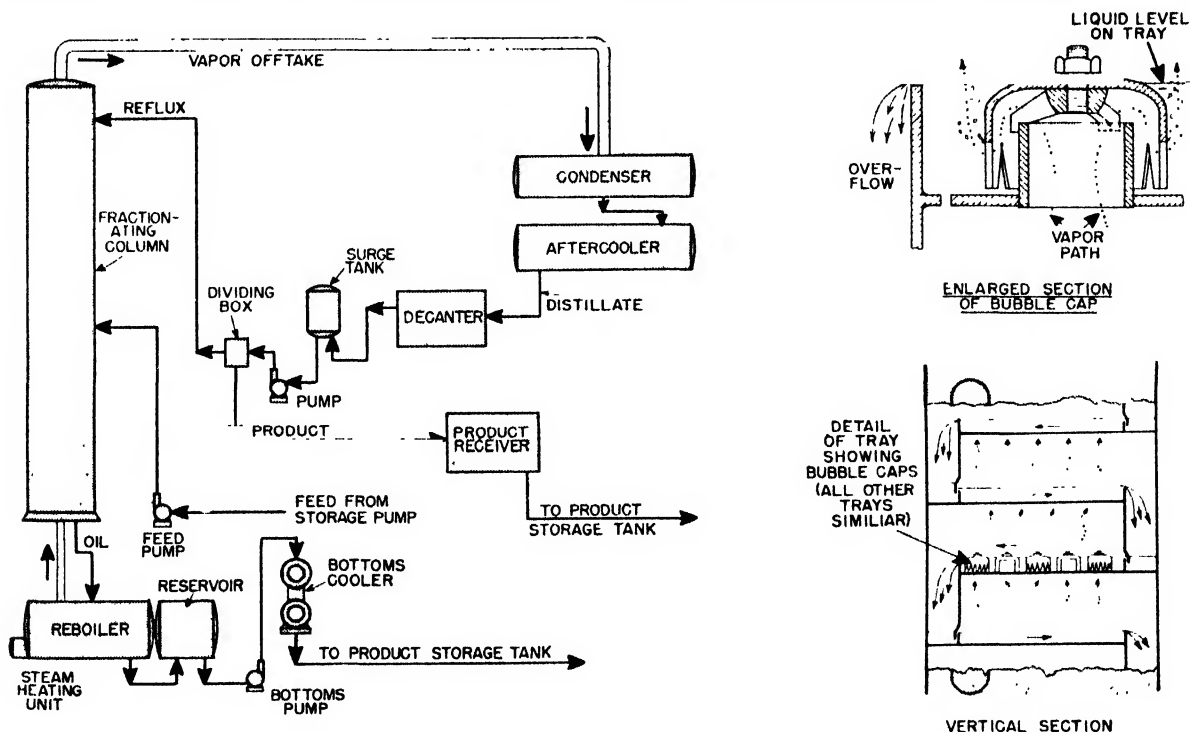

Fig. 5-13. (Left) Schematic diagram illustrating component parts and principle of operation of a modern continuous still. (Right) Schematic details of plates and bubble caps used in stills for fractional distillation. (Courtesy, Smet-Solvay Engineering Division, Allied Chemical and Dye Corporation).

control of the temperature, or this equivalent part may be returned by gravity flow. It is usually the better practice to effect the reflux by pump flow, to provide positive control of this operation.

In the operation of a batch still, the kettle is filled to its designed capacity which leaves space in the upper section to receive the vapors, and the steam is turned into the heating coils. As the material reaches the boiling point, it is necessary to control the rate of steam flow by the pressure or temperature in the kettle. The vapors ascend the column, are condensed in the condenser, and a predetermined amount of condensed liquid is returned to the column. It may all be returned for a while until the column is in product and temperature balance, at which time product may be removed and sent to storage. The vapors are forced into the fractionating column by the pressure in the kettle and pass through the bubble caps on each plate where they come in intimate contact with the downward flow of reflux. This contact provides a series of steps consisting of evaporation and condensation on each plate, and a temperature gradient is developed through the column such that the lowest temperature is at the top and the highest temperature is at the bottom. This temperature gradient in a batch still column is in a constant state of change as the lower-boiling-point materials are first distilled over and replaced with the heavier fractions, but each plate maintains a relative temperature differential between the plates above and below. During the progress of the distillation progressively higher-boiling-point materials are removed with consequent increase in the column and kettle temperatures. Intermediate fractions are always produced between the principal components, benzene and toluene. These products are stored separately and re-run in the still to maintain the maximum recovery of finished products.

Continuous Still Operation—A continuous still (Figure 5-13) consists of a kettle or reboiler of considerably smaller capacity than that of the batch process, because the feed material is being constantly pumped into the unit and the residue pumped out of the reboiler. It is equipped with a fractionating column, a condenser, and reflux control. There is usually more than one still unit in a group, because the hot residue from the first unit is used as feed to the second unit and this arrangement may be carried on with as many units as there are fractions to be recovered.

The feed to a continuous unit is pumped into the side of the fractionating column instead of into the kettle as in a batch still. In a batch still, a number of products are progressively removed from the top of the fractionating column, but in a continuous unit only one product is obtained from the top of a fractionating column, this product having the lowest boiling point of any component in the feed. Accordingly, there must be as many columns as products and intermediate off-grade fractions. The principles of fractional distillation apply to the operation of the column in regard to evaporation and condensation on each plate with a temperature gradient from top to bottom of the column. However, unlike the batch still, the conditions of temperature and pressure throughout the unit in the reboiler and column remain constant, and each plate operates at a constant temperature and pressure.

Control of Distillation Processes—The operations of batch and continuous distillation require control of various factors in the operating unit.

In batch-still operations, the principal control factors are the temperature of the vapor leaving the top of the column, rate of vaporization, and volume of reflux pumped into the top of the column. The vaporization is

controlled by the amount of steam introduced into the heating elements in the kettle, which can be done by hand operation of the steam valve or with a pressure controller actuated by the pressure in the kettle. The reflux provides a control of the temperature gradient in the column and makes it possible to remove in order the various components of the oil being fractionally distilled, the lowest-boiling-point fraction being the first removed. Other control factors are the level of oil in the kettle, rate of flow of product and reflux, temperature of condenser water in and out of the unit, and temperature of distillate.

Continuous distillation requires more control than batch in that all factors must be kept constant. A uniform feed of constant composition to the column is provided with a flow controller. Constant measurements of column temperatures, generally bottom of column, below feed, above feed and top of column, along with temperature of water in and out of the condenser, and temperature of distillate and bottom reboiler fractions, are taken with pyrometric recorders of the potentiometer type. Liquid-level controllers are used to regulate pumping of the bottoms of one still unit to the next still and also pumping of the distillate as it flows from the condensers. The oil vaporization is regulated by a pressure controller automatically operating the steam-header valve. Liquid levels in reboiler, surge and receiving tanks are indicated by instruments. Oil flows through pipe lines are indicated by rotameters and steam flows are recorded.

Type of Refining Process—Plant designs are classified as batch, semi-continuous and continuous, depending on the type of distillation.

Of all of the variables affecting the design of a plant, that of the size of the installation probably has the most bearing on whether the process will either be semi-continuous or continuous. It is not generally agreed just where the dividing point is. Small and medium-sized plants have the semi-continuous design and larger plants have continuous design.

One of the most elementary light-oil refining processes is to acid-wash a crude light oil containing no heavy solvent, and refine it into washed motor benzene, pure benzene, pure toluene, commercial xylenes, and pure still residue by either batch or continuous fractional distillation.

Refinement of light oil of this character would involve acid-washing the crude light oil, then provide settling and storage from which the washed light oil is charged either to batch stills for production of desired grades of pure products, or is fed continuously to the pure continuous stills. The first continuous column, a residue remover, removes the residue from the washed light oil. The second continuous column, a forerunnings stripper, takes off heads of the washed light oil as forerunnings or motor benzene. The third column takes off pure benzene. The fourth column takes off pure toluene with the commercial xylenes as a side cut or they can be pumped from the reboiler and accumulated for a batch distillation.

Residue removal prior to the separation of the oil into its principal components is an improvement in refining since it eliminates impurities in the pure products and the need for treatment of the still vapors or products with an aqueous solution of caustic soda. The continued heating of the residue, if it is a residual product of all the distillations, results in decomposition reactions of the polymerized materials producing sulphur dioxide, which, together with the hydrogen sulphide present, results in free sulphur.

Forerunnings, which are the lowest boiling point con-

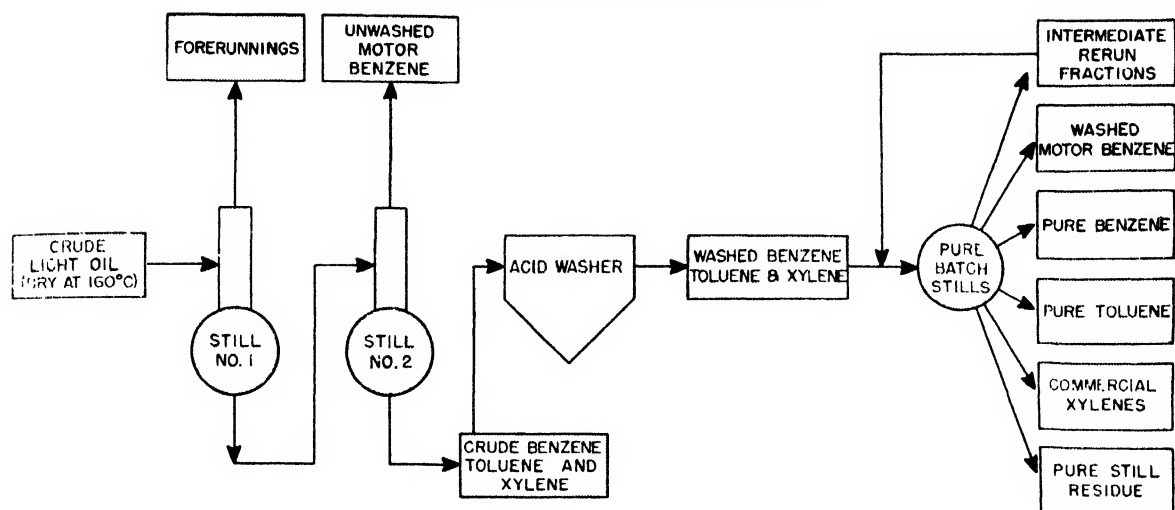

Fig 5-14. Flow sheet illustrating combined use of continuous and batch-type stills in the semi-continuous recovery of the products shown in the boxes at the right. The stills labeled No. 1 and No. 2 are continuous stills.

stituents of the light oil (such as hydrogen sulphide, methyl mercaptan, butadiene, butylenes, amylenes, cyclopentadiene, carbon disulphide, and other compounds) must be removed in any operation with a stripper column if they are present in the oil. This is necessary to produce good grades of motor benzene and pure benzene. If the sulphur impurities are sufficiently low in the light oil, all of the forerunnings can be added to the motor benzene fraction. Unfortunately, non-gum-forming unsaturated hydrocarbons which have good motor-fuel ratings are removed along with gum-forming unsaturates in acid washing.

The semi-continuous process is adapted to refining

light oils which require the removal of forerunnings and in which the production of unwashed motor benzene is desired. The general plan of design with a light oil dry at 320° F (160° C) would consist of two continuous stills followed by as many batch stills as desirable with an acid-washing process interposed between the two distillation units (Figure 5-14). The bulk of the distillation is carried out in the continuous crude stills. The first column is a forerunnings stripper and the second column takes off all or part of the benzene content of the light oil as unwashed motor benzene, the amount depending on the pure benzene requirements.

The motor-benzene fraction thus produced contains

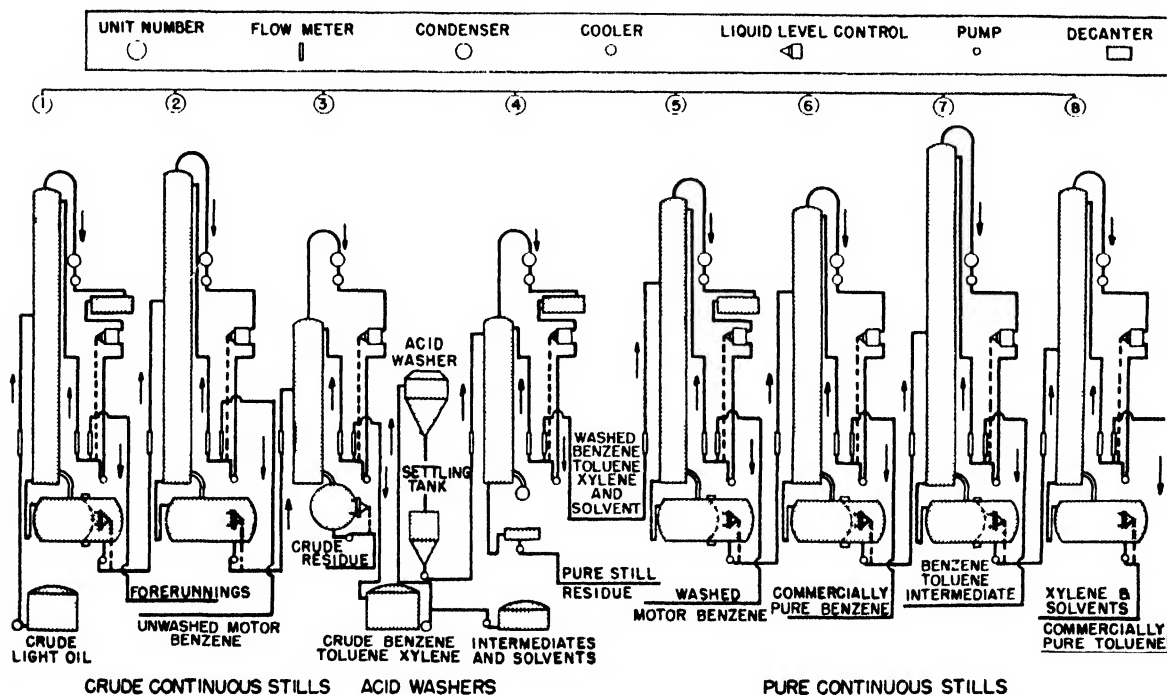

Fig. 5-15. Flow diagram for a continuous light-oil recovery process. (Courtesy, Semet-Solvay Engineering Division, Allied Chemical and Dye Corporation.)

FIG. 5-16. Exterior view of a benzene plant showing distillation columns and other equipment for the continuous distillation of light oil.

impurities which would normally be removed by an acid-washing operation. If allowed to stand, certain of the unsaturated impurities polymerize to form gums which result in trouble in an engine burning such motor benzene. Formation of the gums in the motor benzene is prevented by addition of an inhibitor (an organic anti-oxidant), but none of the unsaturates or other impurities, which are desirable due to their fuel value, are removed by this treatment. After removal of this unwashed motor benzene, the fraction containing the remainder of the benzene, toluene and xylene is acid-washed and batch distilled for production of washed motor benzene, pure benzene, pure toluene and commercial xylene.

If light oil, containing heavy solvents, and having a dry point of 390°F (200°C) is processed, an additional column becomes necessary in the layout. This would be a continuous crude column and number three in the lineup. The overhead of this column would be benzene, toluene and xylene, which would be acid-washed. The bottoms of this column, crude residue consisting of used wash oil, solvents, and naphthalene, would be batch distilled to recover crude heavy solvent. The residue of this batch distillation, containing used wash oil and naphthalene, is processed in crystallizing pans for the recovery of crude naphthalene, while the used wash oil is returned to the wash-oil system.

Another technique used in the smaller installations is to have one batch still in addition to the continuous crude stills and operate part time continuous and finish up with batch operation. In this case, washed oil is fed

to the column and benzene is removed continuously, allowing the toluene and xylene to build up in the kettle. When the kettle becomes filled, the feed is discontinued and the unit is then operated as a batch still, and first the toluene distilled over, then the xylene.

In a continuous process (Figures 5-15 and 5-16), with a light oil dry at 390°F (200°C), the continuous crude unit would have three columns, the first for fore-runings, the second for unwashed motor benzene, and the third for producing the benzene, toluene and xylene overhead for subsequent recovery of pure products after acid washing. The residue, consisting of used wash oil, heavy solvents and naphthalene, is batch distilled.

The continuous pure unit would consist of four columns, the first for removal of pure still residues, the second for stripping the small volume of paraffins and other low-boiling constituents which may be in the washed oil subsequent to pure benzene production on the next column. This column can also be used to remove any part of the benzene content of the oil for washed motor benzene production. The third column produces pure benzene, and the fourth pure toluene as a top product, and xylene with a small volume of heavy solvent as a bottom product. The bottom product is distilled in a batch operation to produce commercial xylenes and a refined heavy solvent.

For the production of additional grades of product, or to remove any intermediates between products, it is necessary to add another column to the design layout since each column produces an individual fraction or product.

SECTION 9

REFINING OF COAL TAR

The volatile products resulting from the thermal decomposition of bituminous coal contain a yellow vapor as a finely divided suspensoid which, upon condensation, yields a black viscous material called coal tar. There are many types of coal tar produced, depending

on the temperature and conditions of carbonization. The coal tar which has the most important commercial significance is that produced during the high-temperature carbonization of bituminous coal. These coal tars consist essentially of aromatic hydrocarbons

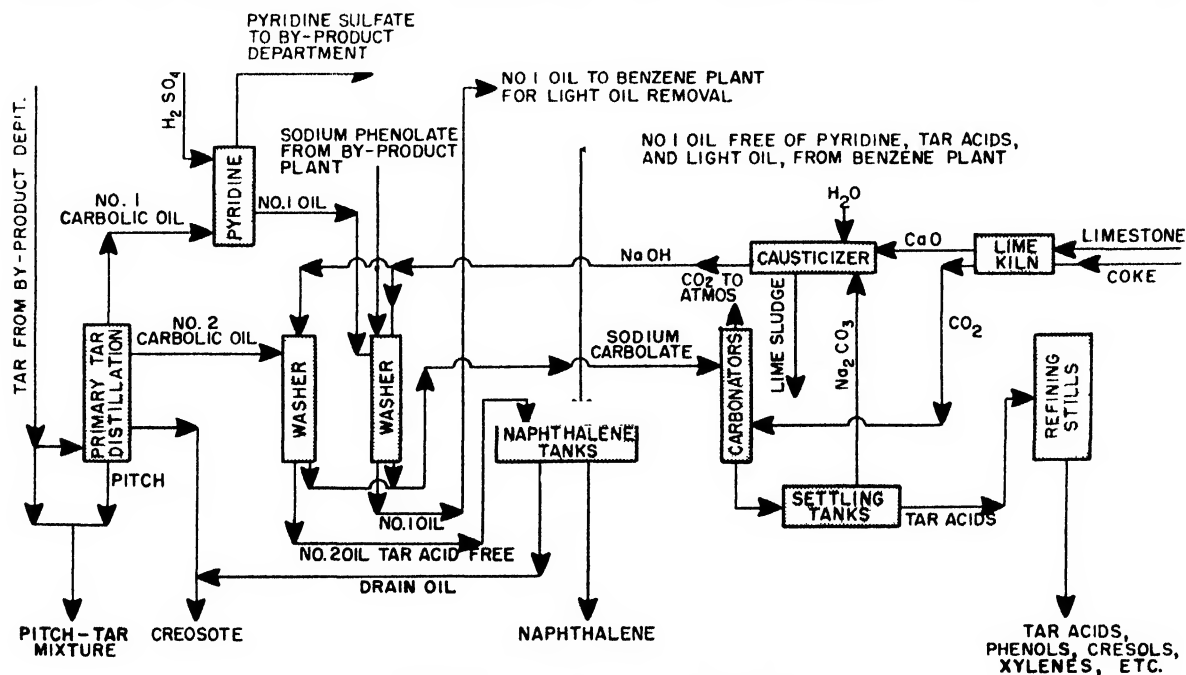

Fig. 5-17. Flow diagram of a tar plant.

which are characterized by ring-type chemical structure and contain such compounds as benzene, naphthalene, anthracene and their related homologues; oxygenated compounds usually referred to as tar acids which include phenol, cresols, and xylenes; nitrogen compounds in which the nitrogen is included in the ring structure such as pyridine, picolines, etc., and only very small amounts of the paraffinic compounds (Table 5-11).

This type of tar is used for the recovery of tar acids, naphthalene, creosote oils, pyridine bases and pitch (Figure 5-17). Their recovery requires the use of fractional distillation of the tar as the first operation, with subsequent use of fractional distillation procedures in some of the other operations, chemical extraction for the removal of acidic and basic compounds with subsequent purification and refining of the extracts, and crystallizing operations for the recovery of such compounds as naphthalene, anthracene, carbazole and phenanthrene.

These operations may be conducted as batch or continuous operations depending principally upon the quantities of material to be processed. The following description is restricted to one procedure that has been found satisfactory and does not necessarily represent operating practices throughout the industry.

Distillation of Tar—The raw tar, which is maintained at a temperature of about 140° F (60° C) in the storage system, is continuously pumped into the tar distillation system (Figure 5-18). In its course through the system, it is preheated to about 300° F (150° C) by indirect heat exchange where it absorbs some of the sensible heat of the creosote oil and pitch. It then enters the bottom bank of tubes in the tar heater where the temperature is increased to about 435° F (225° C) before entering the dehydration column. This column is equipped with three fractionating plates and its function is to permit the water and low-boiling tar oils to be liberated from the hot tar. The water and light oil leaving the top of the dehydration column are condensed and run to receiving tanks where the oil and water are separated by gravity. It is necessary to control the temperature of the column by returning a portion of the condensed oil distillate to the top so that excessive amounts of oil are not removed. This operation is necessary to maintain a differential in the specific gravity of the oil and water whereby the oil is maintained at a density of less than that of the water.

The residue from this column is free of water and leaves the base of the column at a temperature of 355-390° F (180-200° C). It is then returned to the high-temperature section of the tar heater where it is heated to about 750° F (400° C) for the second flash-distillation operation. This operation is conducted in a fractionating tower where the hot tar is transferred to a section near its base and vaporization of the volatile constituents takes place.

The residue is removed from the bottom of the column at a temperature of about 700° F (370° C) whereupon its temperature is reduced to about 390° F (200° C) through heat exchangers to heat incoming raw tar. It is then disposed of according to requirements. Pitch is used as a binder in making carbon electrodes, as roofing pitch, fiber pitch, in the formulation of pipe-line enamels, and as fuel. If it is to be used as fuel it may be mixed with undistilled tar in a special type of mixer in which the foaming due to mixing hot pitch and wet tar can be controlled, or it may be mixed with selected fractions of petroleum oil or such combinations as may be dictated by operating requirements. A liquid-fuel residue may also be produced by reducing the tem-

Table 5-II. Compounds Recovered from Coal Tar and Light Oil*

I. Neutral Compounds		
(From Light Oil)		
Name	Formula	Boiling Point, °C
Benzene	C_6H_6	80.1
Toluene	$C_6H_5CH_3$	110.6
Meta-Xylene	$C_6H_4(CH_3)_2$	139.3
Para-Xylene	$C_6H_4(CH_3)_2$	139.4
Ortho-Xylene	$C_6H_4(CH_3)_2$	144
Mesitylene	$C_6H_3(CH_3)_3$	164.6
Pseudocumene	$C_6H_3(CH_3)_3$	169.2
Coumarone	C_9H_8O	174
Indene	C_9H_8	182.4

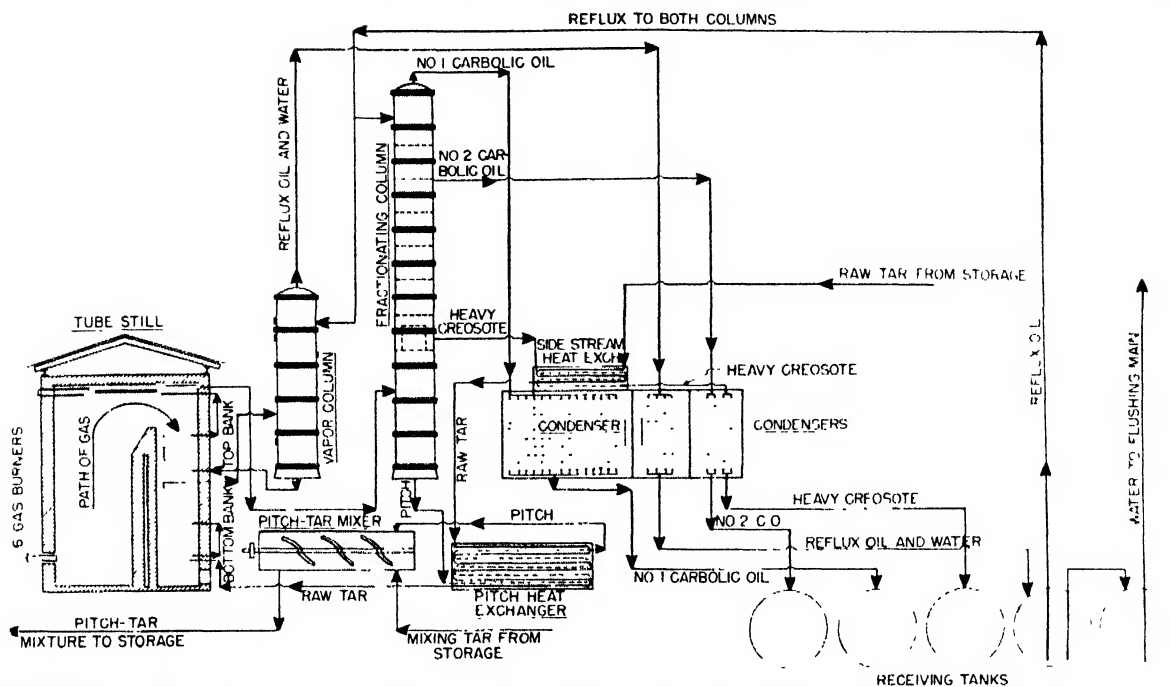

FIG. 5-18. Schematic representation of a primary tar distillation plant. (Courtesy, Foster-Wheeler Corporation.)

perature of distillation to permit the heavy creosote-oil fractions to remain with the pitch, which makes it unnecessary to blend any cut-back material with the residue. It has been demonstrated that this residue is a desirable liquid fuel for open-hearth operations as it has a heating value of 160,000 to 165,000 Btu per gallon.

The vapors passing upward within the column travel through tray sections equipped with bubble caps and downflow pipes to provide a fractional separation of the vapors into the several components with a prescribed distillation range. Reflux is provided by pumping a portion of the light distillate into the top of the column. This reflux provides control of the temperature gradient in the column and makes it possible to remove fractions of definite boiling points from selected trays at various levels in the column.

The operation of continuous distillation requires careful control at all points in the operating unit. The first requisite for successful operation of continuous distillation is a uniform feed of constant composition, which must be followed by careful control of the temperatures and pressures at all points in the system. The control points selected are the inlet and outlet temperatures and pressures of the heating section used for the dehydration operation, and the comparable points for the bank of tubes used to supply heat for distillation of the oils. The temperature at the top of each column must be controlled by regulation of the reflux oil that is pumped into these sections. The temperature of all condensers requires control to prevent the deposition of crystalline compounds such as naphthalene and anthracene.

The pitch removed from the base of the column may have a high solidification point, and its temperature must be controlled to provide easy flow in the pipe lines and heat exchangers.

The distillates recovered are separated into the following fractions: (a) a light-oil fraction (No. 1 carbolitic oil) with a distillation end-point of about 410° F (210° C) which contains, in addition to the normal light-

oil products, tar acids, pyridine bases and some naphthalene, (b) an intermediate-oil fraction (No. 2 carbolitic oil) with a distillation end-point of about 480° F (250° C) which contains tar acids and the major portion of the naphthalene, (c) an anthracene-oil fraction boiling above 480° F (250° C) in which the end-point is controlled by the temperature to which the tar is heated prior to entering the column.

The light-oil fraction is processed for the recovery of pyridine bases and crude tar acids, after which the light oil is removed by distillation and the residual naphthalene is processed for the recovery of salable naphthalene.

The intermediate-oil fraction is processed for the recovery of crude tar acids and then for naphthalene in the same process as noted above for the residual portion of the light-oil fraction.

The anthracene-oil fraction is blended with the drain oil from the naphthalene process for the production of various grades of creosote oil.

The residual pitch from the tar distillation is used for fuel in the open hearths and heating furnaces in the various steel-producing facilities. It is necessary to blend it with fuel oil or virgin tar to lower the viscosity prior to its burning as a fuel. Other uses previously mentioned are in the manufacture of carbon electrodes, roofing pitch, pipe-line enamels, and as saturating pitch.

A description of methods for the processing of the light-oil and intermediate-oil fractions will follow.

Pyridine Sulphate Recovery—Recovery of pyridine bases from tar oils is a comparatively simple process. Essentially, a solution of sulphuric acid is circulated through the oil, combining with the tar bases present to form pyridine sulphate according to the following reaction:

The pyridine sulphate is separated from the oil by gravity.

The first step in the process is dilution of the 60° Bé

sulphuric acid with water in a lead-lined tank equipped with an agitator. A solution containing about 17 per cent of commercial acid has been found to give best results.

About 8,500 gallons of fresh oil is pumped into the washer, along with 1,500 to 1,700 gallons of the acid solution which has been about two-thirds reacted by two previous washes. This effects a partial extraction of the pyridine, and completes the conversion of the sulphuric acid to pyridine sulphate. The crude pyridine sulphate solution is separated from the oil by decantation and is then ready to be rectified. The once-washed oil in the washer is washed again by acid solution which has been one-third satisfied by one previous wash. The oil is finally stripped of remaining pyridine bases by the third wash, using the fresh sulphuric-acid solution.

Rectification of the pyridine sulphate is the final step. It means simply that the sulphate solution is boiled in the rectifier by means of coils carrying live steam, the generated water vapor carrying away the unwanted oil, naphthalene and tar acids in the sulphate. These vapors are condensed and processed for the recovery of tar acids.

The rectified pyridine sulphate is then ready for springing with ammonia and distillation for recovery of refined pyridine, as described previously in Section 6.

The pyridine-free oil which has been separated from the pyridine sulphate by gravity in the washer still possesses a small acid content which must be removed to make it suitable for further processing. A weak solution of soda ash in water (about 12 to 14 per cent) is used for the purpose, giving the following reaction:

The reaction takes place as the oil is continually pumped through the neutralizer containing the soda-ash solution. The sodium-sulphate solution formed in the neutralizing reaction is a waste material and is disposed of in coke-quenching towers.

Pyridine bases also are recovered from saturator liquors, as described in Section 6 of this chapter.

Tar Acid Recovery—It is frequently difficult to make a choice between processes and equipment used in these processes for the recovery of tar acids from tar distillates. The processing steps involved, combinations of equipment used, and descriptions of the equipment follow.

Washing removes tar acids in the form of phenol ($\text{C}_6\text{H}_5\text{OH}$) and phenol homologues from the carbolite oils by simple contact with caustic soda to form sodium phenolate according to the equation:

The washer is a suitably proportioned cone-bottom tank with a spray or other flow-distributing mechanism at the top. Steam-heated coils are provided in the bottom of the washer to maintain fluidity of naphthalene-bearing oils and a desirable reaction temperature of about 167° F (75° C). A mixture comprising 50 per cent carbolite oil and 50 per cent caustic-soda solution (8.5 per cent NaOH) is added to the washer. Caustic is circulated by pump from the bottom of the washer back into the top, filtering down through the carbolite oil by gravity and removing tar acids from the oil by contact. This process is preferred because more violent methods, such as mechanically agitating the oil and caustic together, tend to form emulsions which, on occasion, are almost impossible to separate. Oil and carbolite are readily separated by gravity when no emulsion exists.

Rectifying is a process required to remove undesirable pyridine bases (if not previously removed), oils and

naphthalene from the carbolite or sodium phenolate by boiling, usually under vacuum.

Springing (liberation of tar acids in sodium phenolate solution) can be accomplished by neutralization with sulphuric acid or carbon dioxide gas according to the following reactions:

If sulphuric acid is used, no special equipment is needed except a tank equipped for agitation. Commercial acid is added to the carbolite during agitation to the extent needed to convert all the carbolite to tar acids and sodium sulphate. The tar acids and sulphate separate by gravity.

If carbon dioxide gas is used, more complicated equipment is necessary in the form of a series of 3 to 6 towers packed with grids or baffles. Carbolite pumped to the top of these towers trickles down through the grids, coming in contact with the CO_2 gas which is admitted to the bottom of the column and passes upward countercurrently to the flow of liquid.

Method I (Figure 5-19) shows the minimum plant for tar acid recovery with three items of processing equipment—washer, rectifier and springer. The chief advantage of this plant is the very small investment required. The crude tar acids it produces may contain small quantities of sulphur compounds causing corrosion of equipment in the subsequent distillation of the tar acids.

Method II—The acid springer is replaced by carbon-dioxide springing towers (commonly called carbonating towers), and facilities for the production of lime and caustic soda added. A largely noncorrosive product is obtained at lower unit cost. Coke, limestone and small quantities of soda ash are required which produce the caustic soda for washing of oil and the carbon dioxide gas for springing of tar acids.

The particular virtue of this method lies in the fact that the sodium carbonate initially supplied to the system may be regenerated completely. The production of sodium hydroxide, the formation of sodium phenolate, the liberation of tar acids and the regeneration of the sodium carbonate are shown in the following series of formulas:

Lime (CaO) and carbon dioxide gas (CO_2) are produced in the vertical lime kiln from limestone (CaCO_3) and coke fuel, according to the equation:

Method III, as shown in Figure 5-19, is an all-continuous method in which the procedure and equipment are as illustrated.

Batch Rectifier—The boiling of the carbolite (sodium phenolate) produces a steam distillation which removes small quantities of naphthalene, oils and tar bases which gravity separation in the washers did not remove. The boiling is done under vacuum to permit use of low-pressure steam and to reduce hydrolysis of carbolites to tar acids which would be carried over with the vapors. This is a comparatively simple apparatus, the only design problem being provision of adequate heating and condensing capacities.

Batch Carbonating, or Springing System—The towers (about 25 ft. high) contain steel hurdles or baffles. Carbolite, circulated by pump from the reservoir at the bottom to the top of the tower, trickles down through

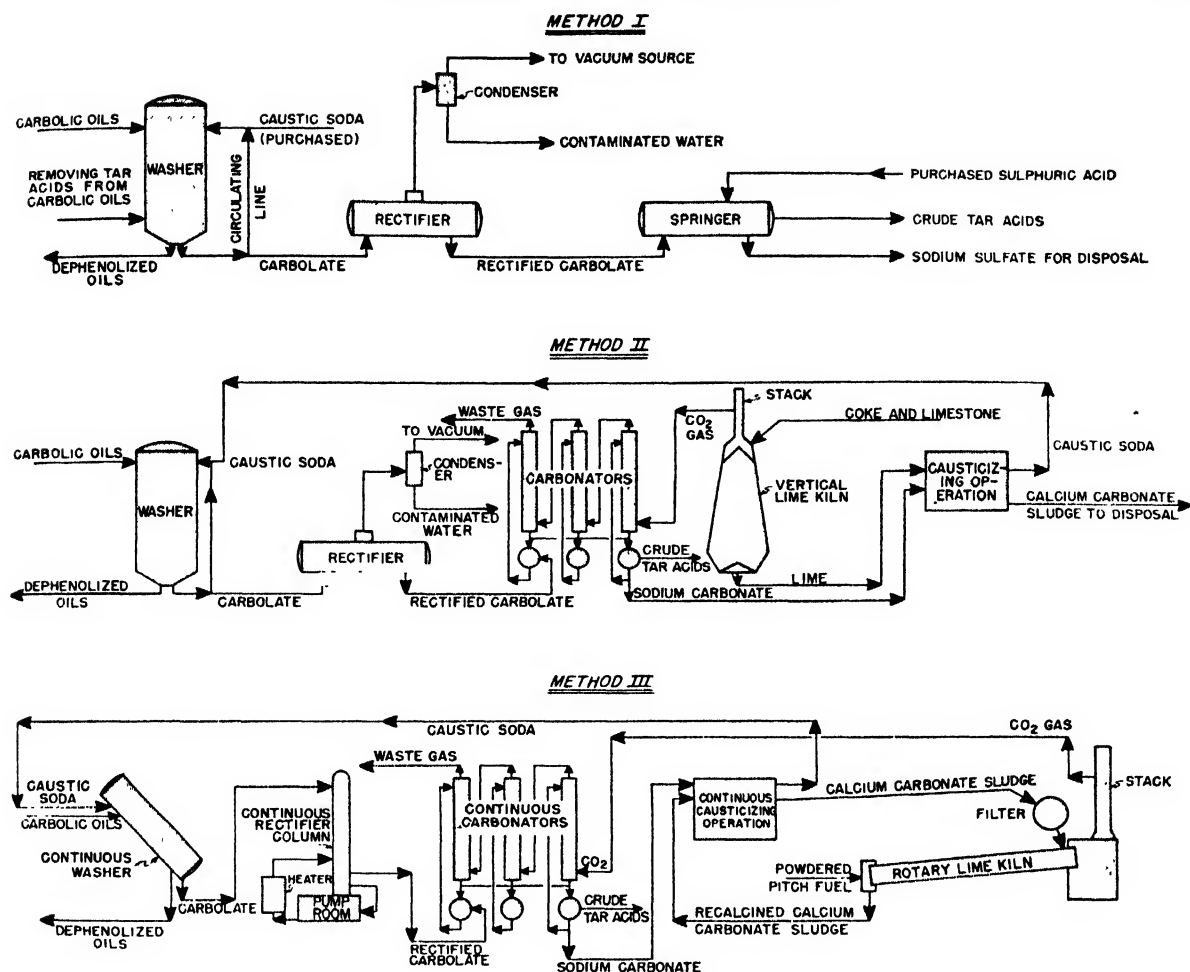

Fig. 5-19. Three methods for the recovery of crude tar acids.

the hurdles to be contacted by the CO_2 gas moving countercurrently to the liquid. The CO_2 gas is delivered to the carbonators from the lime kiln by rotary positive blowers. The following description applies to a system employing four towers.

When the reaction has reached completion in the last carbonator (No. 4), the solution of free tar acids, carbonate and a low concentration of carbolate is pumped from the reservoir, and this reservoir recharged with the solution from the reservoir of No. 3 carbonator. The reaction in this solution has reached the stage of being three-fourths completed, having a higher concentration of carbolate and a lower concentration of free tar acids and carbonate than No. 4 carbonator. In turn No. 2 and No. 1 carbonator solutions are pumped to the carbonators ahead, No. 3 and No. 2 respectively, and No. 1 carbonator is recharged with fresh carbolate. In this way, the highest concentration of CO_2 gas is caused to react with the lowest concentration of carbolate in No. 4 carbonator, while the almost spent gas contacts the strongest concentration of carbolate in No. 1 carbonator. This system of circulation is designed to achieve maximum usage of the CO_2 gas available.

Here, the design problem is mainly one of capacity. If the contact time between liquid and gas is adequate, about 180 cu. ft. of 30 per cent carbon-dioxide gas will suffice to liberate each gallon of tar acid. Since salts have a tendency to build up on the hurdles in the towers, it

is necessary to provide means for removing and cleaning of hurdles. Ordinary materials of construction can be used throughout.

Lime Kiln—In order to reduce to a minimum the carry-over of undesirable salts into the subsequent chemical reactions, limestone of maximum purity is required for the lime kiln, as well as for most other chemical processes. The coke fuel must be carefully chosen as to size in order to be completely and efficiently consumed in the burning area of the kiln.

In operation, limestone and coke in proportions of 8 to 10 pounds of stone to one of coke are charged by skip hoist into the charging bell at the top of the kiln at regular intervals. Burned lime is removed either continuously or intermittently by rotation of the mound-shaped hearth at the bottom. Stack gases pass from the cast-iron acorn (situated at the center of the kiln near the top) to the atmosphere by way of the stack on one side of the acorn, or to the boosters for use in the system by way of the opposite side of the acorn. The reaction taking place in the kiln is chemically expressed by the equation:

or, in other words, limestone plus coke (carbon) plus air (oxygen) produces lime and carbon dioxide gas when heat results from burning of the coke. The stack gases produced are first passed through a cyclone dust

catcher of conventional design and a gas scrubber before taking part in the chemical process. The scrubber is simply a limestone-packed tower into which water is sprayed at the top. The kiln gases, entering at the bottom and leaving at the top, are cooled and stripped of their water-soluble constituents.

Chief design problems for local determination concern facilities for unloading, sorting, screening and proportioning the limestone and coke for charging into the kiln, along with screening, crushing, conveying, storing and distribution of the resulting lime.

Caustic soda (NaOH) is produced by bringing soda ash (Na_2CO_3) and lime (CaO) together in the proper proportions and at the right temperature in the presence of water according to the equation:

Batch Caustic System—A solution of soda ash in water of the desired quantity and strength is added to the batch causticizers (or causticizing tanks), and heated to about 90° C. The necessary quantity of lime is then delivered to each causticizer and agitated by slowly rotating blades. Heat of reaction raises the temperature of the charge to about 98° C. After reaction is complete, agitation is stopped and the batch allowed to settle, the calcium-carbonate sludge settling to the bottom. After settling, the clear caustic soda is skimmed off the top, following which the calcium-carbonate sludge is filtered to recover all possible liquid materials. The filter cake is disposed of to a dump to waste disposal.

This is a comparatively simple and flexible system involving no particular problems of design or materials of construction and can be installed at minimum cost. It presents an operating problem, however, since the heat of reaction when lime is added can readily cause the batch to overflow. Moreover, it is impossible, with this kind of equipment, to prevent carry-over of small quantities of calcium-carbonate sludge with the caustic soda. This entrained sludge distributes itself all through the tanks and processing equipment used in the recovery of crude tar acids, necessitating periodic cleaning of facilities.

Continuous Causticizing System—By this method a predetermined concentration of soda ash in water, together with the proper proportion of crushed lime, is fed continuously into a slaker. A tubular steam heater automatically maintains the soda-ash solution at a temperature of 207° F (97° C) at the entrance to the slaker. The slaker is a rotating cylinder which serves the dual purpose of completely slaking the lime and eliminating large solids such as unburned coke and raw limestone cores. The mixture passes, by gravity, into a classifier which removes small solids. The mixture is pumped from this point to three overhead, cascaded mixers, or causticizers, equipped with agitators which serve the purpose of allowing necessary time for the chemical reaction to be completely finished before entering the thickener. The completely reacted mixture of caustic soda and calcium-carbonate sludge flows into the top center of the thickener, where clear caustic soda is continuously drawn off the top outer rim of the thickener as washed calcium-carbonate sludge is pumped off the bottom. The sludge, after filtering, may be recalcined in a rotary kiln or sent to waste disposal.

This system, while more expensive to build than a batch plant, has the advantage of requiring much less space for a given capacity.

Rotary Kiln—Calcium-carbonate sludge from the thickener is dried in the vacuum rotary filter shown above the charging end of the kiln in Figure 5—19. The filter cake is dropped to a worm conveyor which charges

the cake into the rotating, brick-lined cylinder. Rotation of the slightly inclined kiln moves the sludge slowly toward the discharge end as the burning fuel (coke oven gas in this case), converts the sludge to lime with the same chemical reaction as that which takes place in a vertical kiln. A temperature of about 1650° F (900° C) in the flue is maintained.

The design problem for this type of kiln is exceedingly complex especially where high CO_2 content in flue gases is specified for use in the process.

Tar-Acid Refining—The refining of crude tar acids is a distillation problem similar, in most respects, to the problems discussed at length in benzene refining. Crude tar acids are fractionated to produce the comparatively pure components, usually as phenol, ortho cresol, meta-para cresol, and xylenes. Meta-para cresol is composed of two close boiling compounds, meta cresol and para cresol, differing in boiling point by about one degree Centigrade. Xylenes, composed of six isomers boiling between 410° F (210° C) and 437° F (225° C) and higher boiling tar acids, may be cut into such fractions as the market demands and the distilling facilities permit.

Only two essential items of equipment are involved (other than such obvious items as tanks, pumps and piping), a pot still or heater, and a fractionating column. The number of trays in the columns would be dictated by the degree of purity desired in the finished product. Known installations vary from 40 to 80 trays or plates per column. The present trend is towards more trays to obtain products of higher purity. Distillation can be made at atmospheric pressure or under vacuum.

Horizontal Pot Still—The horizontal pot still consists of a horizontal tank resting upon a brick furnace with about one-third of its surface exposed to the heat. Gas is used as fuel. The arched brickwork of the combustion oven is studded with small flues or perforations which admit the heat to the bottom of the still without exposing the still bottom to direct flame. A disadvantage of this type of pot still is the comparatively small heating surface. Vapors from the boiling tar acids pass through the small dome at the top of the still to the fractionating column for effecting separation in a typical batch distillation process. One of the problems of tar-acid distillation by this process is the necessity for frequent cleaning of salts and decomposition products from the inner surfaces of the pot.

Vertical Pot Still—This is a vertical tank resting upon a brick furnace with about two-thirds of the surface exposed to the heat. Residue removal from the pot is difficult, and the tail pipe (drain line) frequently is difficult to clean and maintain. Direct application of high heat not only causes a certain amount of decomposition of the tar acids with attendant loss of product but also causes burning and rapid deterioration and corrosion of the pot itself; the maintenance is, therefore, high.

Steam-Heated Vacuum Batch Still—The kettle, or pot, is simply a horizontal tank which serves as a reservoir for the crude tar acids and a chamber for the release of the vapors. The contents of the kettle are continuously circulated by pump through a heater and back into the top of the kettle where vapors are released and pass into the bottom of the column for fractionation. Since the whole system is maintained under high vacuum, steam at 150 pounds pressure is adequate as a source of heat. The heater consists of a group of steam tubes around which the flow of tar acids is directed by a series of baffles.

This method of distilling tar acids reduces both decomposition of the material handled and corrosion of

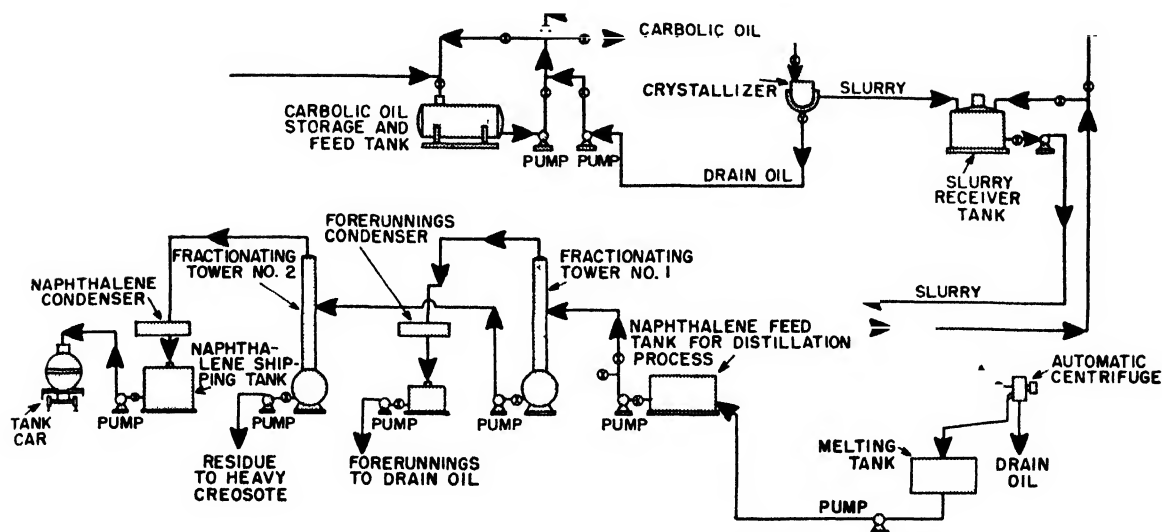

Fig. 5-20. Schematic representation of steps and equipment used in the recovery of naphthalene.

equipment. Standard materials of construction may be used throughout. Use of stainless steel in the vapor line, condenser and product line prolongs life and reduces contamination of products.

Naphthalene Recovery—The distillation of tar produces an overhead fraction consisting of carbolite oil, naphthalene and other neutral oils. Following the removal of tar acids by caustic washing, the remaining oils and naphthalene are pumped to equipment where the naphthalene is recovered by crystallization and/or distillation (Figure 5-20). The crystallization step is necessary sometimes since there are impurities present that cannot be removed by distillation alone.

The crude separation of the naphthalene where crystallization is necessary is accomplished in a series of continuous crystallizer units, each water-jacketed for cooling purposes and equipped with a slow-speed spiral stirrer to keep the crystals in suspension in the oil. The crystallizer feed tanks are maintained at 170° F.

The crude naphthalene crystals obtained from these crystallizer units are centrifuged, melted, and then pumped to the distillation section for refinement. To maintain a uniform feed for the centrifuges, the slurry from the crystallizer units at a temperature of about 70° F is first passed into an agitated slurry tank. From this slurry tank, the slurry is pumped to automatically controlled centrifuges which separate the naphthalene

crystals from the oils in the slurry. Part of this mixture of oils is recycled to the crystallizers while the remainder is pumped to storage. The centrifuged naphthalene crystals, on the other hand, are dropped into melting tanks to be melted by indirect steam and then pumped to a feed tank for the distillation section.

This distillation equipment is designed to refine the melted naphthalene by separating it into a light oil, refined naphthalene and a heavy oil. The first distillation column receives the melted naphthalene from the feed tank, which is maintained at 200° F. This column produces an overhead fraction of light neutral oil which is condensed in a water-cooled condenser and passed to a surge tank; reflux from this tank is returned to the first column at a controlled rate. The residue is pumped to the second fractionating column at a controlled rate. An overhead of naphthalene is produced in the second column and condensed in a water-cooled condenser. The condensed naphthalene is received in a shipping tank maintained at 250° F from which it can be pumped directly to tank cars or tank trucks for shipment. The residue from this second column is cooled to about 250° F and pumped to storage. The neutral oils after naphthalene recovery generally are blended with high-boiling anthracene oils also separated from tar to produce specification grades of creosote oils for use as wood preservatives.

SECTION 10

USES OF COKE, COKE-OVEN GAS AND COAL CHEMICALS

Metallurgical Coke—Coke is used for production of iron in blast furnaces and the coke dust as a fuel for steam generation in boiler houses.

Fuel Gas—After the recovery of coal chemicals, the gas provides fuel for heating the coke ovens, and the excess gas goes to the steel-producing units for heating open hearths and reheating furnaces. When practicable, other gas of lower Btu value may profitably replace the coke-oven gas for firing the ovens.

Ammonium Sulphate—The ammonium sulphate recovered from coke-oven gas is used for admixture with phosphate and potash constituents to provide balanced agricultural fertilizers for the various requirements, or

it may be used for direct application where nitrogen is the only requirement at the time of use.

Phenol—Phenol (C_6H_5OH), sometimes called carbolite acid, is recovered from both coal tar and ammonia liquor, and has the lowest boiling point of any of the tar acids. Its most important use is in the manufacture of resinous condensation products by reaction with formaldehyde, e.g., "Bakelite". As a chemical intermediate it is used in the preparation of synthetic tannins, dye intermediates, perfumes, plasticizers, picric acid, salicylic acid, and in the refining of lubricating oils.

Ortho Cresol—Ortho cresol ($CH_3C_6H_4OH$), another tar acid, is also used in the production of synthetic

resins to control the plasticity of the resin. It is nitrated to produce insecticides and weed killers. It is used in various organic syntheses and in the production of artificial flavors and perfumes.

Meta-Para Cresol—Meta-para cresol ($\text{CH}_3\text{C}_6\text{H}_4\text{OH}$) is a combination of two tar acids with boiling points too close together (394 and 396°F — 201 and 202°C) to permit separation at present with available plant scale distillation facilities. As in the case of the two previous tar acids, its chief use is in the production of synthetic resins and the plasticizer tricresyl phosphate. It is also used in organic synthesis and in the production of insecticides, dyestuffs, pharmaceuticals and photographic compounds.

Xylenes—Xylenes ($\text{C}_6\text{H}_4\text{OH}(\text{CH}_3)_2$) are composed of six isomers, with boiling points ranging from 410 to 437°F (210 to 225°C). Their uses are much like the other tar acids. Commercial xylenes are used as solvents for paints, enamels, varnishes, lacquers, azo dyes, aniline resins, acid proofing and rubber cement. The better grades, 3° and 5° xylenes are used for trinitro-xylene, an explosive, and as raw materials for manufacturing pharmaceuticals, mothproofing agents, perfumes, sulfonic acids and xylol bromide, a poison gas. Some of them find application as flotation oils used in the refining of ores.

Naphthalene—Naphthalene is recovered both from tar and light oil. It has the formula C_{10}H_8 and is one of the most versatile and important of the industrial organic chemicals, being an essential raw material for the preparation of a great many products. It is recognized by everyone in the form of moth balls. Its partial oxidation product, phthalic anhydride, is used quite extensively in the production of resins, lacquers and plastics of various kinds and for dyestuffs for fabrics, paper and paint. Derivatives of naphthalene are used in the manufacture of explosives, soaps, photographic chemicals, wetting agents, insecticides, disinfectants and pharmaceuticals, synthetic tannins, oils, fuels and in organic syntheses, all of which include only a part of its widespread present and potential application.

Creosote Oil—Creosote oil (from coal tar) constitutes a large part of the distillate from tar, and is a blend of different fractions to meet specifications established by the American Wood Preservers Association. Practically all of it goes into the pressure impregnation of wood, such as piling, telephone poles and railroad ties.

Pyridine Bases—The pyridine bases produced from the lighter tar oils include pyridine ($\text{C}_5\text{H}_5\text{N}$), the picolines ($\text{C}_5\text{H}_4\text{N}\cdot\text{CH}_3$), lutidines ($\text{C}_5\text{H}_3\text{N}\cdot(\text{CH}_3)_2$), and some quinoline ($\text{C}_8\text{H}_7\text{N}$).

Pyridine is an excellent solvent and is used as such in the rubber, paint and plastic industries. It is a basic material for chemical organic synthesis of industrial compounds, such as piperidine, etc. It is also used in the production of chemicals for waterproofing fabric and as

a carrying agent for impregnation of the fabric with the waterproofing agents.

The picolines are also basic materials for organic chemical syntheses. It is also used for production of nicotinamide and niacinamide, both vitamin substances used for augmenting the vitamin content of various foods and also as direct treatment for dietary deficiencies.

Pyridine bases are recovered from saturator liquor as well as tar.

Pitch-Tar Mixture—Pitch, mixed with virgin tar in proportions that will maintain fluidity, is an open-hearth fuel. Pitch is also employed as a binder in making carbon electrodes, roofing pitch, fiber pitch, and in pipe-line enamels.

Forerunnings—The forerunnings from light-oil refining contain cyclopentadiene, which can be processed to produce dicyclopentadiene. The polymerized products are useful as plastics and resins for use in paints and protective coatings.

Pure Benzene—Recovered by refining light oil, benzene is industrially the most important member of the aromatic family. It is used for the manufacture of a large proportion of all the coal-tar dyes, styrene monomer for synthetic rubber and polystyrene, aviation gasoline, dichlorobenzene and synthetic phenol. Plastics such as nylon, alkyd and polystyrene resins are end products derived from pure benzene. It is a chemical raw material for organic chemicals and is used as a general solvent.

Motor Benzene—While large quantities have been used in the past as an automotive fuel, its present use for this purpose has greatly diminished. It has a high anti-knock rating and has been used for this purpose on various occasions.

Pure Toluene—Toluene is used for the production of trinitrotoluene (T.N.T.), an explosive. Some use is found in the production of sulfonamide-formaldehyde resins for lacquers and adhesive formulation. It is a solvent for varnishes, waxes, resins, lacquer stains, enamels, dopes, cellulose esters and ethers. It is used by the oil-cloth industry, as a degreasing agent for bone and hair, as an extractant for animal and vegetable oils, and for printing ink and artificial leather. It is a raw material for chemicals and various dyes.

Crude Heavy Solvent—Crude heavy solvent is the source of coumarone-indene resins, which are thermoplastic resins used for rubber compounding, floor tile, printing inks, lacquers and chewing gum. It is used for ship-bottom paints, pipe coatings, shingle stains, wire enamel, brake linings, and bituminous and other dark-colored paints.

Refined Heavy Solvent—Refined heavy solvent is used in slow-drying solvents for manufacture of shoe polish, flat wall and interior paints, house paints, printing ink and enamels. It also is used in the linoleum industry.

Chapter 6

IRON ORES

SECTION 1

ORES AND THE IRON-BEARING MINERALS

Minerals and Ores—Any homogeneous inorganic substance having a fixed chemical composition or a definite range in composition and occurring naturally in the solid state is called a **mineral species**. A mineral, therefore, may be either an element or a compound of two or more elements. A few elements, like gold and platinum, occur for the most part native. Others, like silver, copper, mercury, sulphur, and carbon, may be found both native and combined. Most minerals, of which more than 1,500 species have been discovered and named, such as quartz, feldspar, hematite, hornblende, calcite, mica, etc., or their varieties, represent definite chemical compounds. A natural deposit of but a single mineral is seldom encountered in nature because the many forces at work usually produce conditions favorable to the creation or co-existence of more than one mineral in the same environment. While such a deposit is of course ideal, most natural deposits of which the ores are constituted are comprised of several minerals, the undesirable ones collectively being termed the **gangue** of the ore. In general, then, an **ore** is defined as a mineral or a mixture of minerals from which one or more elements may be extracted with profit.

The Iron-Bearing Minerals—There is a vast number of mineral species that contain iron. Only a few are of any importance commercially, because, in most cases, either the iron content is too low to justify the extraction of the metal or the mineral itself does not occur in sufficient abundance to make it available for use as an ore. Grouped according to their chemical composition, the iron-bearing minerals of chief importance are divided into four classes; namely, the iron oxides, iron carbonates, iron silicates, and iron sulphides. Of these, only the first and second classes may be considered as a factor in the manufacture of steel in the United States at present, although silicates have some promise of being used when cost factors change.

Table 6—I. Chief Iron-Bearing Minerals

Chemical Name	Mineralogical Name
1. Ferrosoferric Oxide	Magnetite
2. Anhydrous Ferric Oxide	Hematite
3. Hydrous Ferric Oxides	Limonite and others
4. Ferrous Carbonate	Siderite
5. Iron Silicates	Chloropal and others
6. Iron Sulphides	Pyrite and others

Magnetite Group—The only important mineral of this group is **magnetite**, chemical formula Fe_3O_4 , composed of iron, 72.4 per cent, and oxygen, 27.6 per cent. It varies in color from gray to black, has a specific gravity of about 5.0, and is magnetic. Advantage is taken of this last named property in locating ore bodies below the surface of the ground, and in mechanically purifying

ores of this group by magnetic concentration. Magnetite is often found closely associated with igneous rocks, in which case it is likely to contain appreciable amounts of chromium or titanium oxides which cannot be removed from it by magnetic concentration. In beneficiation operations, the ore is crushed to the fineness required, placed on a broad belt, and passed over a strong magnet, usually revolving. The revolving magnet holds the magnetic ore on the belt until after the non-magnetic gangue has dropped off into one chute, then the ore can be collected in another chute. Only about 5 per cent of the world's supply of iron is obtained from magnetite.

Hematite Group—The typical mineral of this group is hematite, which contains the equivalent of 70 per cent metallic iron, based on the chemical formula Fe_2O_3 . It furnishes the base of the world's most important ores. Being associated with rocks of various geological periods, these ores occur widely distributed, and in a variety of forms, which differ greatly in their iron content. Many of these varieties are known from their outstanding characteristics as, **red hematite**, **specular hematite**, **öolitic hematite**, **fossil ore**, and **Clinton hematite**. The last sometimes contains enough lime to be self-fluxing. The pure mineral has a true density or specific gravity of about 5.0 but the specific gravities of its ores vary from about 1.6 to 5.0 due to porosity.

Limonite or Brown Ore Group—Limonite is a field term generally referring to natural hydrous iron oxides whose real identity is unknown. Ores of the limonite group contain variable amounts of water and they do not all conform strictly to the preceding definition of mineral species. As a group they may be represented by the general formula $\text{Fe}_2\text{O}_3 \cdot n\text{H}_2\text{O}$. The most common member of the group, **goethite** is a definite mineral species with the formula $\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$. Terms applied to the other members of this group in order of their progressive increase in water content are **turgite**, **limonite**, **xanthosiderite**, and **limnrite**. On a theoretical basis, the iron content of this series will vary from 52.31 per cent to 66.31 per cent. Their true densities vary from 3.6 to 4.7, and the apparent densities of their ores from 1.5 to 4. These minerals are widely distributed throughout the world.

The Carbonate Group—The representative member of this group is the mineral known as **siderite**, or iron carbonate, FeCO_3 , which has a density of about 3.5 and contains 48.3 per cent iron. Owing to the fact that carbonic acid is dibasic, a part of the iron required to neutralize it may be replaced by other metals, thus giving rise to a series of minerals, such as iron-calcium carbonate, iron-magnesium carbonate, etc. Some of the names commonly applied to these ores are **spathic iron**

Table 6—II. Major Available Iron Ores *

* Data from sources believed to be reliable

** Mainly natural Fe

x-Concentrates

ore, black-band ore, etc. Usually, carbonate ores are calcined before they are charged into the blast furnace. Frequently, they contain enough lime to be self-fluxing.

The Silicate Group—Iron silicates are of more interest as original sources of iron ores than as sources for iron. Like the carbonates, the silicates may be double salts in which iron forms only a portion of the base. Silicates in which iron forms the principal base include *chamoisite*, *chloropal*, *cronstedtite*, *hisingerite*, *stilpnomelane*, *greenalite*, *minnesotaite*, *grunerite*, *daphnite*, *thuringite*, and others. Silicates are not mined as a source of iron except when they occur associated with other iron-bearing oxides.

Distribution and Supply of Iron Ores—Table 6—II is an attempt to indicate the wide distribution of iron ores, the kinds of ore and the estimated available supply for each country of the world based upon data from many sources believed to be reliable. Available ores include those which can be mined and used in their natural state, and those amenable to beneficiation by present methods at a cost to compete with natural ores. In addition there is an even greater potential supply that includes ores which, on account of their geographical location, chemical composition, or physical condition, cannot be commercially exploited in competition with available ores by present methods of beneficiation, transportation and smelting. The table shows that the world supply of available ore is roughly 35,000,000,000 tons and that while about 1/14 of this supply lies within the United States, other countries are also well supplied; some so well that strong competition in the iron and steel business is assured. However, the business does not rest upon ore alone, but also upon coal, fluxing materials, refractories and water, all of which are required in the manufacture of iron and steel. Even with all these raw materials available or close at hand, much depends on the ingenuity, resourcefulness, and

intelligence of the men who make the products and manage the business, and especially of the people of the nation so favored. Table 6—III summarizes the average proportions of annual production of iron ore by continents.

Due to various causes, such as interruption by war, change of political control, change in share of world markets, depletion of deposits, and others, in certain countries, there have been shiftings of the above proportions among the nations of the earth. For example, United States production was half of the world's total for the year 1947.

Geologic Range of Iron Ores—Just as iron ores have a wide geographical range, so do they have a wide geological range. They are found in the oldest rocks of the earth's crust (Pre-Cambrian), as well as in the most recent, and in rocks of most of the geologic periods between these two extremes. Even today, iron-ore minerals are being formed in some of our existing bogs, lakes, and oceans, though these have no commercial importance at present. A summary of a few of the world's important iron-ore occurrences, but including a few little-known deposits for purposes of illustration, together with their location and the geological age of the rocks in which they are found, is shown in Table 6—IV. The largest deposits presently producing are those of the Lake Superior Region, the Bihar and Orissa Provinces in India, and Quebec-Labrador, all of Pre-Cambrian Age.

Formations Associated With Iron Ores—Besides showing a wide distribution geographically and geologically, deposits of iron are found associated with almost all the principal types of rocks. That is, they occur in formations of igneous, metamorphic, and sedimentary origin. The form and shape of the deposits are, to a certain extent, governed by the types of rocks in which they occur. Deposits exist generally as irregular and lenticular shoots in schists and igneous rocks and as flat-lying, tabular beds in the sedimentary formations, as, for example, the Wabana ores of Newfoundland.

The Lake Superior ores, the Alabama ores, and the Minette ores of Luxemburg, France, and Germany, are in sedimentary rocks, the Lake Superior ores being found in jaspers, cherts, and slates, and the other two in calcareous sandstones and shales. On the other hand, the magnetic ores of Kirunavaara, Sweden, are found in syenites and quartz porphyries, while the ores of Chile occur in diorite and diabase, both occurrences being in igneous rocks. Metamorphic rocks in the form of granitic and syenitic gneisses enclose the ores of Northern New York and New Jersey.

Origin of Iron Ores—Naturally, the form and mineral content of iron ores are closely allied to their rock associations and to their mode of origin. By the latter term is meant how the iron-bearing minerals as now found were introduced or concentrated in the rocks now enclosing them. It is a curious fact that although deposits of these ores have been extensively studied and worked for years, and though they rank among the most common of metallic ores, opinions as to the mode of origin of numerous deposits are wide and varied.

This diversity of opinion is, in part, due to the ever-changing and increasing knowledge of geology and its allied sciences, principally physics and chemistry, for the natural concentration and development of iron-bearing minerals are dependent upon the physical and chemical laws of nature.

The methods of formation and natural concentration of iron ores may, for simplicity, be divided into two classes:

Table 6—III. Average Proportion of Annual Production of Iron Ore By Continents.

Continent*	Per Cent	
	Average of 1935 to 1938, Inclusive	Average of 1946 to 1951, Inclusive

* Well known, important deposits.

1. Ores concentrated through the action of mechanical forces.
2. Ores formed by chemical action and physical change.

In the first group the iron minerals, together with other detrital material (sands, etc.), were set free by the weathering and disintegration of rocks formerly containing them. This detrital material was then transported mechanically by streams or the waves of the sea and redeposited in layers or beds richer in iron content than the rocks from which the iron minerals were derived. The concentration thus brought about is made possible by the fact that the higher specific gravity of the minerals containing iron caused their deposition sooner than the other lighter sands, which were carried farther on. Thus originated most of the stream and beach placer deposits of magnetite sands, as well as some of the sedimentary hematite deposits of iron ore now mined. The deposition in these cases generally occurred in stream beds, lakes, bogs, and along the seacoast.

In the second group, two methods of concentration are involved:

- (a) Crystallization of the minerals from a silicate melt or magma.
- (b) Precipitation from solution carrying iron, by reaction within the solutions or between the

solutions and the rocks penetrated by them (replacement).

In the case of crystallization from a magma, the iron minerals, being heavier, tend to be segregated by gravity during the process of their crystallization from the cooling of the silicate melt, with the result that the final igneous rock may contain certain areas richer in iron minerals than others. It is in this manner that the magnetite deposits of Kirunavaara, Sweden, and the Adirondacks Region of New York, are supposed to have been formed.

Where precipitation from solution is involved, the iron ores are either introduced or concentrated later in the rocks in which they are now found, or formed contemporaneously with them. The solutions may either be descending ground waters or ascending hot waters and gases, the latter of which accompany or follow some period of igneous activity. These waters, in passing through the rocks, enrich them in iron materials, where iron ore is being formed, either by precipitating these minerals in the rocks, or by removing the gangue or waste minerals from a rock formation already containing some iron minerals so that the latter are thereby concentrated into an ore. An example of enrichment by introduction of minerals to a formation is the deposition of magnetite in limestone as at Cornwall, Pa. Enrichment by leaching of gangue material is exempli-

fied by ores of the Lake Superior District, where the silica of the iron formation has been removed, leaving the hematite behind to form ore.

Where the silica has not been removed by natural leaching, the iron formations still exist in their original, metamorphosed state. These unleached formations, commonly referred to as *taconite* in Minnesota and *jaspilite* or *Jasper ores* in Michigan, are now the subject of intense metallurgical research directed towards methods of economically removing the silica and concentrating the iron minerals.

Besides the formation of iron materials through the agency of ground waters, they are also precipitated from the waters of lakes, streams, and oceans, the precipitation being either chemical or through the action of minute bacteria. In these cases, the iron is generally accompanied by other sedimentary material such as sands or calcium carbonate, and the result is beds or layers of iron-rich sandstone or limestone. Thus have originated many of our sedimentary iron ore deposits such as those of Birmingham, Alabama, or the Minette ores of Luxemburg, France, and Germany.

SECTION 2

VALUATION OF ORES

The Mineralogical Make-Up of Iron Ores—As was indicated at the beginning, an ore deposit at best represents but a mixture of different minerals, only a part of which will contain the element or elements sought. All iron ores, then, may be looked upon as being made up of these two parts: One part is composed of the iron-bearing minerals, which represent definite compounds of iron; the other part includes all the other substances mixed with these compounds, and is known as the gangue of the ore. Evidently, the richness of the ore, by which term is meant the proportion by weight of iron to all other elements in the ore, depends on the composition of the iron-bearing minerals it contains and upon the amount of gangue associated with them. In working up the ores, their physical condition must also be taken into consideration. In this respect, they are subject to the widest variation, ranging from soft claylike or earthy matter to hard, compact masses. Both extremes tend to give trouble in the blast furnace. Thus, the soft, fine ores are so apt to choke up a furnace not designed to use them that they were once considered practically worthless. The successful smelting of these ores represents one of the great achievements of American furnacemen. One objection to very fine ores, and one that has not yet been overcome, is that they give rise to large amounts of flue dust, which interferes seriously with the economical utilization of the furnace gases. On the other hand, the very hard and dense ores, which enter the furnace in the form of comparatively large lumps, are difficult to reduce and require an excessive amount of fuel for two principal reasons: first, the lumps make an open charge above the zone of fusion, which generally leads to channeling; second, the large dense lumps offer so small a surface to the gases that there is very little reduction of ore by the CO in the gas. Both conditions permit the ore to descend to the fusion zone before much reduction occurs. Here the temperature is so high that reduction must be effected by direct action of carbon upon the oxide with the formation of carbon monoxide, a process that requires about twice as much fuel as the indirect reduction with CO. To improve the reducibility, the ore must be crushed to a maximum size of 2 inches and screened, as described in Section 4.

Factors in the Valuation of Ores—Omitting relative property valuations, prices of competitive ores, costs of transportation, and other considerations of a purely business nature, the chief factors that determine the value of an ore are its richness, its general chemical composition, and its physical make-up. The last factor has been sufficiently discussed above. The richness of the ore will, of course, be made the chief basis for the valuation. For this purpose a unit system is employed, a unit of iron corresponding to one per cent. But the

prices of ores, while generally following closely in proportion, do not rise and fall parallel with the number of units of iron they contain, because the gangue to be disposed of must also be considered. For example, suppose two hematite ores containing 63 per cent and 42 per cent iron are being considered. In the first, 90 per cent of the ore is iron oxide, leaving only 10 per cent as gangue to be disposed of, but the second represents only 60 per cent iron oxide with 40 per cent of its weight as gangue to be fluxed and transported. Next to richness comes the consideration of the chemical composition of the ore as a whole, for certain impurities, such as sulphur, when present in only relatively small amounts, may make a rich ore worthless. Without taking the time to consider all the possibilities in this connection, the more common impurities in ore may be classed as follows:

1. Those impurities that are never reduced in the blast furnace and so do not affect the composition of the iron are alumina, Al_2O_3 ; lime, CaO ; magnesia, MgO ; oxides of sodium (Na_2O), potassium (K_2O), and the other alkali metals; and rare-earth-metal oxides. Most of these substances, it will be observed, are strong bases, with the exception of alumina which may be either an acid or a base. Therefore, the presence of these substances in the ore may not be objectionable, for the lime and the magnesia, in particular, are valuable as fluxes. Alumina also, up to about 5 per cent, may play a useful part in regulating the blast furnace. The alkalies for the most part are driven off with the flue dust, and with modern appliances they may be recovered as a by-product, when present in sufficient amount to justify the installation of the necessary equipment. Usually, the alkalies are not worth the cost of recovery.

2. Those impurities that may be partially reduced in the blast furnace and give elements that enter the pig iron are silica, or the silicates, the sulphates, the selenates, titania, and compounds of manganese, chromium, vanadium, cobalt, columbium, zirconium, and other of the more rare elements. Of these, the silica, which term includes both the free silica and the silicates, constitutes a large part of the gangue of most ores, and as it requires an equal weight of lime or magnesia to flux it, it must be considered in fixing the value of an ore. Owing to the fact that the amount reduced in the blast furnace is subject to control to a considerable extent and that the element is readily removed during the process of purifying the pig iron, it is not considered of much importance from the standpoint of its effect on the steel produced from the iron. This attitude toward silica is just the opposite of that displayed toward the sulphur compounds. All these compounds are reduced in the furnace to sulphides, in which form the sulphur enters either the metal as ferrous or manga-

nese sulphides or the slag as calcium sulphide. Now, there is a limit to the quantity of sulphur a given slag can absorb, less than 5 per cent with the usual slags, and, naturally enough, the nearer this limit is approached, the more difficult it becomes to keep the sulphur out of pig iron. Since more than comparatively small amounts of this element are undesirable in most steels, and it can be removed in steel making only partially and with much difficulty, the importance of this element in fixing the value of an ore is evident. As to the manganese compounds, the amount of this element that enters the iron varies with the manganese content of the ore and takes place to the extent of nearly 75 per cent of the manganese charged. The per cent of this element is, therefore, considered in its relation to the iron content. An ore is available for the manufacture of the ordinary grades of pig iron when the manganese content does not exceed 2 per cent of the iron content, and for steelmaking grades it is preferably kept below 1.5 per cent iron with less than 0.75 per cent being most desirable for the bessemer process. With manganese between 2 per cent and 10 per cent, calculated on the same basis, it is necessary (except for a few grades of merchant iron) to mix the ore with others containing little of this element; but if the manganese content is 15 per cent to 35 per cent of the iron content, then the ore becomes available for the manufacture of spiegel. Since manganese is oxidized in the manufacture of steel, and its reduction consumes fuel, the reasons for these limits are self-evident. Therefore, ores containing 2 to 10 per cent manganese should be classed as **manganiferous iron ores**; those with 10 to 35 per cent manganese, as **ferruginous manganese ores**; and those containing more than 35 per cent manganese, as **manganese ores**, though 48 to 50 per cent is necessary to produce standard 80 per cent ferro-manganese, which represents the form of this element most valuable in the manufacture of steel.

3. **The impurities that are always reduced in the furnace and alloy with the iron** are all the compounds of arsenic and phosphorus. Fortunately, arsenic is not common in iron ores, but phosphorus is always present. While this element is easily removed from the metal by basic processes, none is eliminated by the acid processes, with the result that acid steels contain a higher percentage of this element than the average of the charge from which the steel is produced. This element, therefore, is the basis for the separation of all ores into the two great classes, known as **bessemer** and **basic**. This division, like that for manganese, is made on the basis of the relation of the phosphorus content to iron content of the ore. Since it is desirable to produce bessemer steel that will contain not more than 0.100 per

cent of its weight as phosphorus, a true bessemer ore would be one, the phosphorus content of which, plus the phosphorus content of the coke and limestone required to smelt and flux it, would produce a pig iron with a phosphorus content not exceeding 0.090 per cent. Allowing 10 per cent for conversion loss, such a pig iron would give a steel containing less than 0.100 per cent of its weight of phosphorus. Other elements, the compounds of which are reduced in the blast furnace, include such metals as nickel, copper, zinc, cadmium, indium, tin, etc. Metals like zinc and molybdenum, the oxides of which are volatile at temperatures slightly above or below their reduction temperature, may not all remain in the iron, and may be very objectionable in the furnace, as is zinc, which destroys the furnace linings.

Water or moisture is another factor to be considered in the valuation of ores, because it adds to the weight of ore to be handled and transported. The importance of this matter in fixing the value of an ore is seen at once when it is pointed out that many of the soft ores of the Lake Superior Region carry as much as 12 per cent of their weight as hygroscopic water, and a few as much as, or more than, 15 per cent. Some ores, such as the bog ores, may contain as much as 25 per cent water. This moisture content for any particular ore is much more nearly constant under varying weather conditions than might be expected; but in the case of different ores there is a wide variation, ranging from 0.40 per cent in some of the hard hematites to 16.80 per cent in a few of the soft red ores. Admixtures of certain soft red hematites and limonites sometimes contain in excess of 20 per cent moisture. These points are well illustrated by Table 6—V, the examples of which have been selected because they show about the same iron content when dry.

The marketing of the ores and all the metallurgical calculations involving them are based on the composition of samples dried at 100°–105° C (212°–221° F). It will be observed that drying at this temperature may not drive off water of crystallization and that in the case of the brown hematites a much higher temperature than the drying temperature is required to drive off all the combined water.

Accessibility—It is evident that the economic importance of an ore deposit depends to a great extent upon its size and its location, both geologic and geographic. Thus, an ore, that is very desirable from the standpoint of chemical composition and physical condition, may be so located as to be practically inaccessible; or, granting it can be made accessible, the amount of ore in the deposit may not justify the expense of opening it up. On the other hand, a poor ore may be so con-

Table 6—V. Compositions of Ores, Illustrating Dry and Wet Basis

veniently located that it may be smelted in its natural condition or concentrated at a profit. A thorough discussion of this topic cannot be undertaken in the brief space allotted to this chapter. Suffice it to say, that the working of any ore body under modern conditions

presents difficult engineering problems, both in mining and in transportation, and to these may be added one or more beneficiation operations which include mixing, crushing, screening, concentrating, and agglomerating in various combinations.

SECTION 3

IRON ORE DEPOSITS OF THE UNITED STATES

The Main Producing Districts—Just as a wide diversity is found in geographical and geological distribution of the iron ores from a world viewpoint, so are like conditions found in the United States, for ores of all types and geological associations are encountered here. In two of the main producing districts the ores are found in sedimentary formations. Of these, the one is centered around Birmingham, Alabama, and the other is in the Lake Superior Region, including parts of Northern Minnesota, Wisconsin, and Michigan. The first district produced, in 1953, about 7 per cent of the iron ore of the United States, while the second, the largest iron ore region in the world, produced about 81 per cent (see Table 6—VI). A more detailed description of these areas is given below.

Besides the Alabama and Lake Superior deposits, several other regions contribute their share of the total tonnage. Among these are the magnetite ores of Pennsylvania which occur in Paleozoic limestones cut by diabase dikes of Triassic Age. They contain also a small percentage of copper in the form of chalcopyrite. Another interesting area is the Adirondack Region of New York which also produces a magnetite ore. The latter occurs as irregular masses and lenticular shoots in granites, syenites, and gneisses of Pre-Cambrian Age. Titaniferous magnetite ores of similar association and occurrence also are found here, but they are worked at only one place and there principally for recovery of titanium with iron as a by-product. The magnetite ores of Northern New Jersey and Southeastern New York are also similar to those of the Adirondack Region and occur in granitic, syenitic, and dioritic gneisses in the form of podlike shoots which

are more or less parallel to and interfoliated with the banding of the gneisses, and pitch in the same direction as the minerals of the gneisses themselves. The western occurrences of iron ore are principally magnetite, though those of Sunrise, Wyoming, are hematite. The western magnetites come principally from Iron County, Utah, their occurrences being more or less similar in that they are found in Jurassic limestone at or near the contact of the latter with monzonitic intrusives. Table 6—VI lists the iron ores produced in the United States during 1953, together with the percentage of the total each district produced:

**Table 6—VI. Iron Ore Mined
in the United States During 1953**
(Gross Tons of 2240 Lbs.)

District	Type of Ore	Tonnage Produced	Per Cent of Total
Lake Superior	Hematite	95,655,105	81.1
Southeastern U.S.A.	Hematite	7,691,745	6.5
Northeastern U.S.A.	Magnetite	5,161,813	4.4
Western U.S.A.	(Magnetite) (Hematite)	8,868,658	7.5
Undistributed (by-product ore)	Pyrites Sinter, etc.	617,448	0.5
Total		117,994,769	100.0

SECTION 4

THE BIRMINGHAM DISTRICT

LOCATION, GEOLOGY AND GENERAL DESCRIPTION

Hematite—The most important iron-ore deposit of the Birmingham District is the red hematite ore of the "Big Seam," which occurs in the Clinton formation of Silurian Age. The Clinton formation is approximately 200 feet thick and, in addition to the Big Seam, consists of shales, ferruginous sandstones and some ferruginous limestone. The Big Seam outcrops near the crest of Red Mountain and is of workable thickness (8 to 16 feet) and grade for a distance of about fifteen miles, or from Birmingham to about two miles southwest of Bessemer (Figures 6—1 and 6—2). Near the surface, the ore dips about 22° to the southeast, but, at present mining depths, levels off to about 10°. The leached, or oxidized, ore near the surface has been exhausted, and current mining operations are in the dense, hard ore, under from 1000 to 2000 feet of cover. The ore continues for an undetermined distance under the Cahaba Coal Field.

The ore is an original sedimentary deposit of both fossiliferous and oölitic hematite. The iron content of run-of-mine ore varies from approximately 34 per cent in the southwest end to about 40 per cent. The alumina (3.0 to 3.5 per cent), magnesia (0.40 to 0.80 per cent), phosphorus (0.25 to 0.35 per cent) and manganese (0.14 to 0.16 per cent) do not vary appreciably, but the silica and lime change progressively from about 10 per cent SiO₂ and 18 per cent CaO in the southwest to 21 per cent SiO₂ and 11 per cent CaO in the northeast. Thus, some of the ore is more than self-fluxing but most of it requires additional flux. The relatively low iron content of the ore is partially offset by the presence of the lime, and smelting is economically feasible because of the proximity of suitable coking coals and fluxes. The phosphorus is not high enough for producing iron to use in basic Bessemer converters, but much steel is produced by an acid-Bessemer—basic-open-hearth duplex process in which a high-phosphorus slag is formed that is prepared for use as an excellent soil conditioner as discussed in Chapter 7.

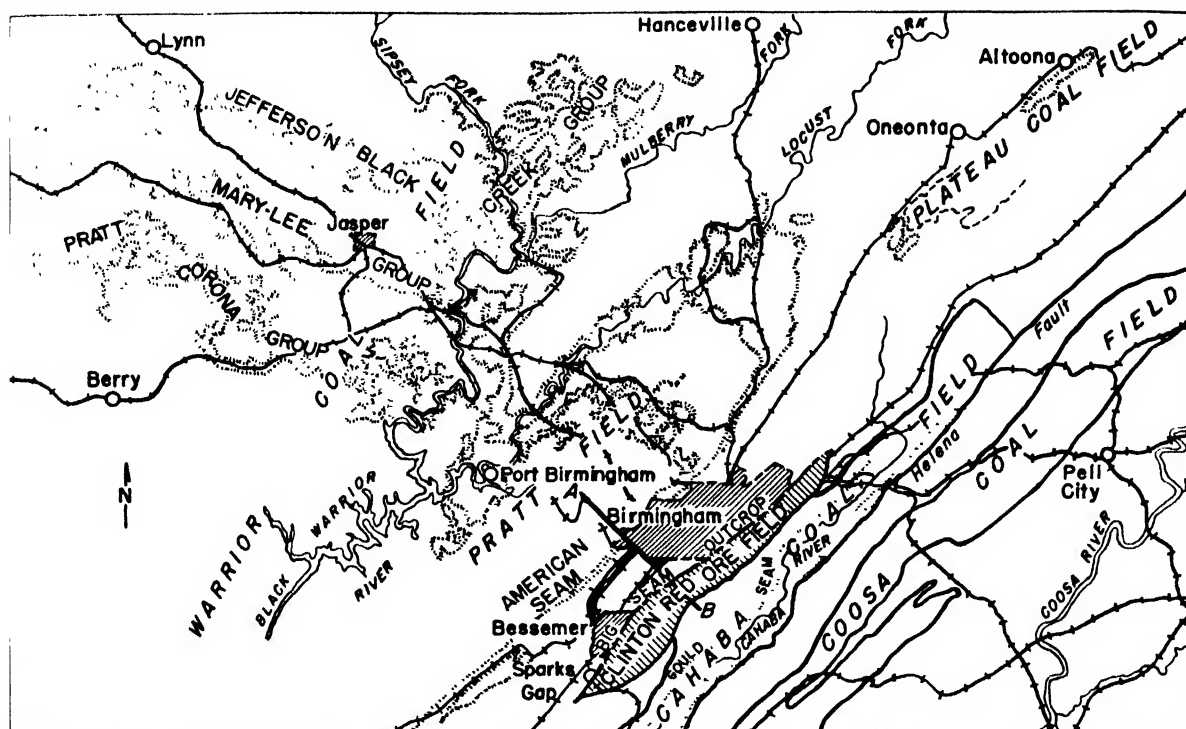

FIG. 6-1. Geological map of the Birmingham, Alabama, mineral area. (See Figure 6-2 for Section AB.)

This ore is mined underground by mechanized room-and-pillar methods generally, and in some operations by stoping methods.

In the mechanized room-and-pillar operations, panel sections approximately 450 feet in width and in varying lengths up to 2000 feet or more are mined. Triple parallel entries are turned off main haulageways at intervals of 450 feet between each set of entries. Haulage track is laid in the middle entry for the operation of mine cars. Rooms are driven from the upper entry into the ore bed at varying angles to afford favorable grades for the mining equipment. Drilling is done at the working faces with air-operated long-feed drills mounted on rubber-tired drill carriages equipped with movable arms to which the drills are attached. Positioning and moving of the arms is by hydraulic control. The broken ore from blasting is loaded with mobile loaders equipped with caterpillar treads. The gathering arms of the loading machine sweep the broken ore to a flight conveyor back of the arms from which it is discharged into rubber-tired shuttle cars maneuvering at the rear of the loader. The shuttle cars transport the ore over varying distances up to 500 feet to discharge points at the panel entry track where mine cars are filled.

In the stoping operations, the method used at mines where the ore bed is too steeply pitching for mechanized room-and-pillar methods, working levels or headings are driven at approximately 230-foot intervals, then "stopes," or rooms, are driven between the levels to recover the ore. Sufficient ore is left in place to form pillars for roof support. After the ore is shot down in the stope, cable-drawn scrapers drag it down the stope, over a steel ramp, and into mine cars. Electric locomotives haul the cars to collecting pockets above the main slope, whence it is drawn into 16-ton skips and pulled to the surface by steam- or electric-driven hoists.

Due to the low iron content of the local ores, pro-

visions have been made for the receipt and storage of foreign ores having high metallic values, for mixing with the local ores to provide richer metallic feed to the blast furnaces, thereby increasing iron production. The characteristics of these ores vary a great deal, but generally the iron content ranges from 61 to 64 per cent, phosphorus from 0.04 to 0.09 per cent, silica from 0.8 to 7.0 per cent, alumina from 1.3 to 1.6 per cent and manganese is fairly constant at 0.04 per cent. The moisture content varies from less than 1.0 to 12.0 per cent and the fines ($-\frac{1}{4}$ inch) from 30 to 70 per cent. Foreign ores are received by vessel at the Port of Mobile and transferred by rail or river transport to the Birmingham district. These ores are processed directly through the ore-conditioning plant in the same manner as the local ores, or sometimes stored for later use. The storage area is provided with a railroad-car shake-out, disposal conveyor and transfer tower, from which 23-ton diesel haulage trucks can carry the ore to assigned stockpile areas, or the ore can be diverted to a surge pile adjacent to the recovery hopper. Recovery of ore from "live" storage is by bulldozer, pushing into the recovery hopper, feeding an inclined conveyor which enters the main plant at a point where secondary crushing is performed. Recovery from "dead" or remote storage is by dragline or shovel loading into the large trucks which dump into or near the recovery hopper.

Limonite—The limonites, or brown ores, of the district are of Cretaceous Age and lie unconformably in scattered deposits on top of Cambrian and Mississippian limestones. The most important of the deposits are those southwest of Birmingham near the Jefferson-Tuscaloosa County line, and northwest of Birmingham at Russellville. The deposits are near the surface and are worked by stripping and open-pit operations. The ore as mined is mixed with about three times its volume of sand, clay and rock and is separated from

this "muck" by log washers. These ores contain no lime. The iron content varies from 40 to 55 per cent, while the phosphorus or the manganese may be from 0.10 to over 1.00 per cent. The brown ores are not sufficient to support the district, but they do make an important contribution to the iron-ore tonnage. Furthermore, with proper selection, they are useful, within certain limits, in controlling phosphorus and manganese contents in pig iron.

Beneficiation of Red Ore (Hematite)—The Tennessee Coal and Iron Division of United States Steel Corporation operates from five to seven mines in the Red Mountain Formation, the product from each mine being of different chemical composition, as indicated above. This presents a problem in burdening blast furnaces. Furthermore, definite economies in operation of the furnaces by the use of uniformly crushed and sized ore have been established in the district. Accordingly, a Central Ore Conditioning and Sintering Plant, located near No. 7 Wenonah mine, about midway of the mining operations, was put in operation in 1940 (Figure 6-3).

The run-of-mine ore (in large lumps) from the various mines is brought in 70-ton cars to this plant and dumped, two cars at a time, by a revolving car dumper. The ore passes through one of two 42-inch gyratory crushers set at 5 inches, and then through one of four 7-foot Symons cone crushers set at approximately 1 inch on the close side. All the ore from these secondary crushers, 70 per cent of which is now minus one inch, is taken by one belt over a conveyor scale, then discharged into a receiving bin in the screening building. This bin contains dividing plates and "hog-backs," which, together with vibrating feeders, portion the ore out to six 6-foot by 14-foot double-deck vibrating screens, where it is screened to three sizes: coarse ($+\frac{3}{4}$ in.), medium ($-\frac{3}{4}$ in., $+\frac{1}{4}$ in.), and fines ($-\frac{1}{4}$ in.). This screening is possible because the ore is dense and usually contains only about $1\frac{1}{2}$ per cent moisture. The product is about 55 per cent Coarse, 20 per cent Medium and 25 per cent Fines.

Each size is sampled by an automatic sampler, the sample being about 0.5 per cent of the total ore. Each sample is prepared for the laboratory in this same building by a series of crushers and cutters, and the three samples from each mine are analyzed promptly so that the results may be used in properly blending the ore.

The coarse and medium ores are weighed on conveyor scales and taken by belt conveyor to the silo storage bins, of which there are forty-eight of 800 tons capacity each, twenty-four being for coarse and twenty-four for medium. The ore from each mine run is kept separate in the silos, and after the results of analyses are received, it is blended with ore from the other mines. This is done by proportional feeders, which always carry a uniform load in terms of pounds per foot of belt, but which can be run at various speeds, so that ore from several silos may be run onto the same belt to produce one blend of uniform excess acidity (excess acidity equals silica plus alumina minus lime). The coarse and medium ores are discharged to separate belt conveyors, which transport them to railroad cars for shipment to the furnaces, the outgoing ore being automatically sampled in the same manner as the incoming ore to furnish a sample for check analysis. Shipment of ore is made on a regular schedule to conform to blast-furnace consumption, the ore being hauled by the company's own railroad over the "High Line," which traverses the valley at a fairly uniform slope from Wenonah to Fairfield and Ensley.

FIG. 6-2. Cross-section of Birmingham Valley iron ore fields (Section AB of Fig. 6-1).

FIG. 6.—3. Central ore-conditioning and sintering plant, Tennessee Coal and Iron Division of United States Steel Corporation.

Sinter Plant—The fine ore from the screening plant is taken by belt conveyor over scales to the storage bins at the sinter plant. There are 33 of these bins, each of 350 tons ore capacity, sixteen bins being used for the ore from the screening plant, ten for flue dust (150 tons per bin), coke breeze (80 tons per bin), or other materials received from outside the plant, and seven which will receive either outside or intra-plant materials.

The fine ore and flue dust are fed from these bins by proportioning feeders to conveyor belts for transporting the proper mix to the sinter plant. Arrangement is also made so that the fine ores alone may be blended and loaded out for stocking purposes without interfering with the sinter-plant operation.

The flue dust in this district contains roughly 30 per cent iron and 15 per cent carbon, which is the chief source of fuel in the sintering operation, although coke breeze and quenching-pit cleanings are also used. The feed must be proportioned to contain the proper amount of carbon, and this varies with different ores, type of sinter desired, etc. At this plant the carbon in the mix is usually about 4.5 per cent.

The conveyor carrying the feed to the sinter plant first passes the discharge end of the sintering machines, where hot undersize sinter, that has been screened out of the sinter discharge chute by a $1\frac{1}{4}$ -inch grizzly, is charged on top of the feed. These return fines amount to about 25 per cent of the feed to the machines and are necessary in the operation to help maintain the porosity of the sintering bed. The proper amount of this circulating load is determined by experiment and may sometimes be as high as 40 per cent.

The sinter feed and the superimposed return undersized sinter are delivered to a paddle-type double-shaft pug mill wherein the revolving blades pre-mix the feed materials and then pass them on by conveyor to the distributor.

The sinter plant proper consists of three Dwight-Lloyd type continuous-grate machines, so that it is necessary to split the feed three ways. This is done by a revolving distributor which gives a full flow of the belt momentarily to each machine. This avoids the segregation that would occur if it were allowed to split itself naturally in three directions. A small receiving hopper and vibrating feeder eliminate the surges that would otherwise occur.

From the distributor, the feed goes to a revolving drum-type pug mill (one for each machine) which thoroughly mixes and aerates it. Water is also added at

this point, if necessary. A certain amount of water must be in the mix in order to maintain the bed porosity, and the proper amount is determined by experiment. About 6 to 8 per cent total moisture is required here, but in plants using ores with higher natural moisture, the figure would, of course, be considerably higher.

The mix feeds out of the pug mills continuously over 24-inch belts to swinging spouts over the machines. The mix strikes a wear plate first, slides off to a feeder plate and then falls to the advancing hearth of the sinter machine evenly, being distributed over the width of the hearth by the swinging motion of the spout.

The sinter machines are 72 inches wide. The one first installed is 89 feet, 3 inches long, with a rated capacity of 50 tons per hour, and the other two machines are each 102 feet long and rated at 60 tons per hour. The machine consists of a series of "pallets" or metal frames, 72 inches by 24 inches mounted on four wheels. Grate bars cover the bottom, and sides of steel plate 12 inches to 14 inches high are provided on the short side, but the other two sides are open so as to form a continuous hearth as the successive pallets push each other along the guide rails. The pallets are picked up from the bottom, or return side, by a large sprocket which then forces them to pass the length of the machine. As they pass under the swinging spout, the feed mix is distributed over the hearth, the larger pieces of feed rolling off by a plate to the desired depth, usually 12 to 14 inches. The pallets then pass under the ignition furnace, which consists of a burner extending the width of the machine. Wing plates of fire brick also serve to reflect the heat down to the bed. Natural gas with forced air is used here for ignition, but other fuels such as blast-furnace gas, coke-oven gas or fuel oil are also satisfactory.

The pallets then travel over the wind boxes, which make up most of the length of the machine, the ignition furnace being over the first wind box. Air is sucked through the bed and the wind boxes by a centrifugal fan of 144,000 c.f.m. capacity at 24-inch static water pressure. The fans, one for each machine, are driven by 1000-h.p. synchronous motors.

Ignition of the sintering bed occurs only at the surface, and as the pallets progress over the wind boxes, this burning, or sintering, zone moves downward through the bed until it reaches the grate bars. The speed of the machine is so regulated that, when the bed is sintered through, the pallet is at the discharge end

of the machine, where it goes over a circular guide, dropping the sinter onto the discharge chute, which contains the grizzly for removing the necessary return fines. The sinter going over the grizzly is discharged directly into railroad cars and is taken to the furnaces as scheduled along with the coarse and medium ore.

The actual sintering process lasts for a few moments only and can occur at the temperature of incipient fusion, which causes the fine particles to agglomerate. Higher temperatures cause a slagging action or positive fusion and result in "hard burned" sinter. During the

process, the carbon is burned off, the CO_2 associated with the lime is driven off, and some of the Fe_2O_3 is reduced to Fe_3O_4 . This results in an increase in iron content from 36.25 per cent in the fine ore alone to about 41 per cent in the sinter, with a yield of about 80 per cent. The action of the combustion air and gases causes a porous structure in the sinter. The relative merit of sinter and natural ore as a blast furnace charge material has been the subject of much discussion, but there is no doubt that sinter is superior to the fine ore from which it is made.

SECTION 5

WESTERN IRON ORES

Iron ore deposits in the western United States exist in Utah, Colorado, Nevada, Wyoming, New Mexico and California. Deposits of commercial significance, with respect to the manufacture of pig iron, are at present known to exist in Wyoming, Nevada, Utah, California, and New Mexico. Western iron-ore mining by United States Steel has been confined to deposits in Utah and only these Utah deposits are discussed herein.

Presently known Utah ore deposits of substantial size are located in the southwestern section of Utah some fifteen to forty miles west of Cedar City and some two hundred miles south of the Geneva and Ironton plants. The most extensive commercial deposits are in the Iron Springs Mining District (now considered as the Pinto-Iron Springs District.) There are

also extensive showings in the Bull Valley District. The general locations of southern Utah ore deposits are indicated in Figure 6-4, on which the Pinto District is identified as "Iron Mountain Deposits" and the Iron Springs District as "Granite Mountain and Three Peaks Deposits."

To date, most of the exploratory work on Utah deposits and practically all of the development work has been confined to the Pinto-Iron Springs District.

Origin of the Utah Ores—In the Iron Springs District, neither the ores nor the country rock show the features characteristic of contact metamorphic deposits. One explanation of the origin of the deposits is that during the intrusion of monzonite porphyry stocks, the hoods and overlying rock were fractured, causing a sudden

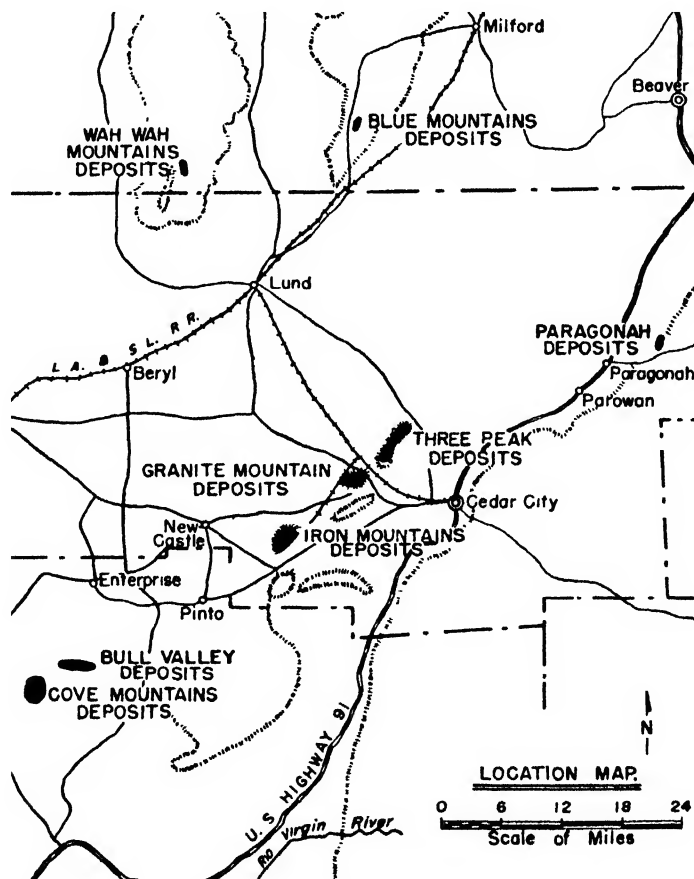

FIG. 6-4. Locations of Southern Utah iron-ore deposits.

release of pressure and liberating FeCl_2 and H_2O gas from the stocks which were still at a high temperature. These gases found ready egress to the surface along tension fissures without appreciably heating the country rock. They deposited magnetite and hematite in the fissures and replaced the contiguous fractured limestone. The period of gas emanation was brief and the hydrothermal stage probably evolved during the later magmatic history never reached this area. The deposits were formed under a cover of less than 5000 feet.

General Geology of the Utah Mining Districts—In the Pinto-Iron Springs District sediments of Jurassic, Cretaceous, and Tertiary ages have been intruded (in early Miocene) by large masses of monzonite taken to be laccoliths. Erosion following the intrusion developed mountains out of the laccoliths, with surrounding rings of outward dipping sediments on the lower slopes. Later extrusion of lavas locally covered the eroded laccoliths and sediments. The lower slopes and flats adjacent to the laccoliths are covered by the usual unconsolidated deposits of the Great Basin country. Faulting, principally of the tension type, is prevalent. The sedimentary sequence in the area includes, from the base upward, the Homestake limestone, Entrada sandstone shale, Iron Springs sandstone, and the Claron sandstone, limestone and conglomerate.

The Homestake limestone is a dark, bluish-gray limestone of a dense texture with relatively uniform characteristics throughout its entire extent, except near the laccolithic contact. The bedding of the Homestake limestone is very indefinite and is easily confused with secondary fracturing; where it is well defined, the limestone is generally thin-bedded.

The Entrada formation is about 250 feet thick and is composed of interbedded shales, sandstones and arkosic sandstones.

The Iron Springs formation is a sandstone probably more than 3000 feet thick which is composed of sandstone, shales and some limestones.

The Claron formation is a pinkish limestone overlain by pink to red shales and conglomerates.

The essential geological features of the Bull Valley District are believed to be the same as those in the Iron Springs District—a series of laccoliths with sediments dipping in every direction away from them, in the manner of a dome surrounded and overlain by flat-lying lavas, the whole being bounded on north and west by later flows of basalt. The contour of the district is rougher than that of the Iron Springs District and the evidences of volcanism are more conspicuous on account of the presence of basalt flows and cinder cones. The mineralized zones are less regular than in the Pinto-Iron Springs District and consist of fissure fillings and irregular replacements.

Occurrence of the Ores "In Situ"—In the Pinto-Iron Springs District, the iron ores occur in disconnected masses within a general area about three miles wide by twenty-three miles long, running northeast and southwest through the district. Figure 6-4 shows the outcroppings of ore (as dark irregular spots) on Iron Mountain, Granite Mountain, and Three Peaks.

The ore deposits for the most part lie at or near the contact of the monzonite laccoliths and the Homestake limestone, which occurs primarily on the eastern, western and southern slopes of foothills of the Three Peaks, Granite Mountain and Iron Mountain, but some of them, as on Iron Mountain, appear at or near the tops of the mountains. Some of the ore does not appear at the surface at all, being covered by sediments and/or monzonite detritus washed from the upper slopes.

In rare instances, replacement is noted in the shales and sandstones of the Entrada and Iron Springs formations which overlie the Homestake limestone.

Ore bodies in the district range in size from small pods of little consequence to bodies containing many millions of tons. The greater part of the ore of the district occurs as limestone replacement deposits on the contact of the monzonite. Vein-type deposits are small. The vertical range of known ore bodies is from surface

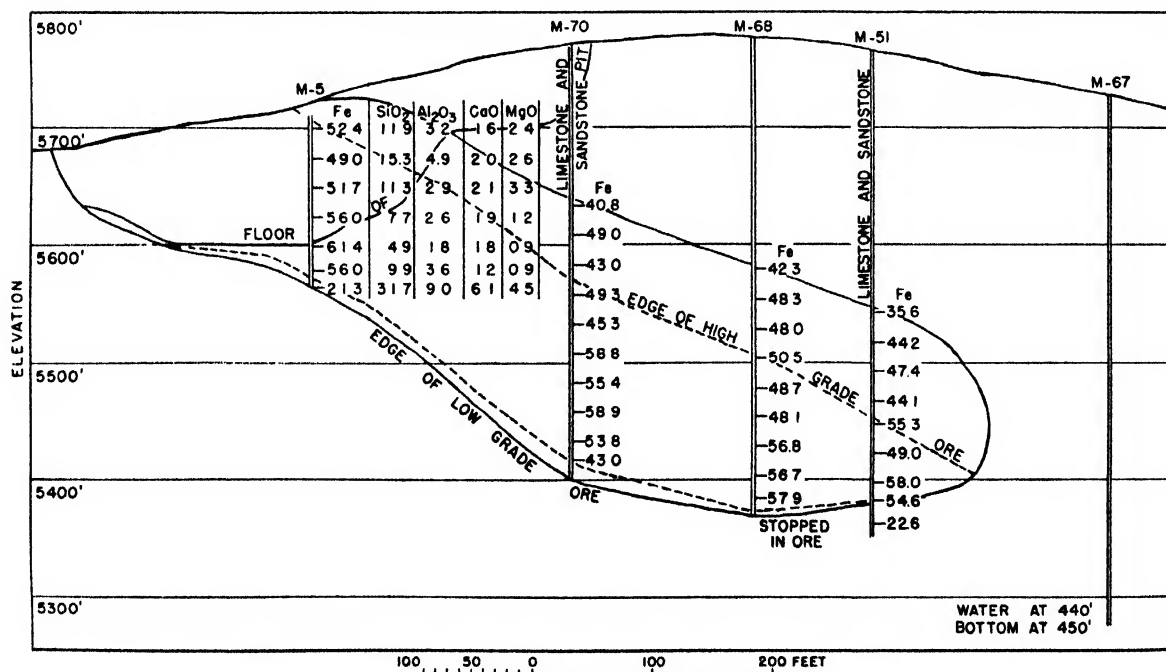

FIG. 6-5. North-south section through an open pit, Pinto-Iron Springs District. Figures show composition of samples taken at 25-foot vertical intervals.

exposures to bodies overlain by over 1300 feet of overburden. Figure 6-5 shows a north-south section through one of the pits in the Granite Mountain area.

In the Bull Valley District, the ore outcroppings are found in an elongated tract about three miles long and a mile and one-half wide. The ore deposits are discontinuous and are similar in some features to those of the Iron Springs District. The principal deposits lie within the monzonite associated with limestone fault blocks, and subordinate ones follow the main contact of the monzonite.

Ore Types—Two distinct types of ore occur in the Pinto-Iron Springs District, namely, the replacement type and the vein type.

The **replacement type**, which includes almost all of the large ore bodies, consists of hematite associated with magnetite and minor amounts of unreplaced limestone, quartz, chalcedony, calcite, barite, apatite, and pyrite. In texture, it is a fairly soft, black, fine granular mixture with occasional ribs of hard, dense material. It is usually magnetic in varying degrees. Ore bodies, where tested, contain 10 to 50 per cent magnetite. Wide variation in magnetite content within the ore body is common. The silica content of replacement ores is relatively low. Local variation of silica within the ore body is more pronounced than the variation in average contents of different ore bodies. Alumina, magnesia, and lime are fairly evenly distributed and of a grade to be ideally suited for fluxing. Sulphur is erratically distributed. It is concentrated locally in the form of pyrite and barite. However, almost all ore bodies in the district are very low in average sulphur content. Phosphorus is found in varying amounts in all ore bodies of the district. Future grading of these ores is likely to be based upon iron and phosphorus contents. The phosphorus, like the sulphur, is also distributed erratically throughout the ore body, seemingly concentrated near faults or fissures. A marked increase in the phosphorus content is noted as the northeast end of the district is approached.

Ores mined in the Iron Springs District in the period 1923 to 1953 averaged 53.99 per cent Fe (weighted average) on a natural weight basis.

Manganese, arsenic, titanium, and zinc are present only in very minute amounts. One ore body in the district, where sampled, contains about 1 per cent copper (from chalcopryite). Other bodies show copper in very minute amounts.

Ore bodies of the replacement type generally are homogeneous masses of a fairly even grade of iron. In some, the periphery is a zone of varying thickness of lower-grade iron, but in most cases the mineralized contact is sharp and distinct. Some areas exist wherein mineralization grades into the Entrada formation above and into the monzonite below. Inclusions of unreplaced limestone occur within some ore bodies, but these are not common. The ore is soft and can be easily crushed.

Vein type ore can be considered as ore from true fissure veins in the monzonite and as ore from contact veins between the monzonite and the sedimentary rocks. Contact veins are rare. They usually extend as replacement ore bodies into the limestone with characteristic changes in mineralization. Vein-type ore is predominantly magnetite with some hematite, limonite, and minor amounts of quartz, apatite, and calcite. The ore is hard, dense, crystalline, massive, and highly magnetic. It is very high in grade and exceptionally low in impurities. It has been used very successfully as charge and feed ore in open-hearth steel manufacture.

The ore in the Bull Valley District is both magnetite and hematite, as in the Pinto-Iron Springs District, but

the hematite on the lower slopes takes on a fine granular texture and a steel-blue color which is not seen in the Iron Springs District.

Development and Mining Practice—The existence of extensive iron-ore deposits in southern Utah was discovered in 1849-1850 by an exploratory party of Mormon pioneers. Soon after discovery of the ores, construction was commenced on a stone blast furnace near Cedar City. This furnace produced small quantities of iron in 1855; however, the fuel, transportation, and labor problems prevented continuation of the operation. A small furnace was erected in the Iron Springs area in 1874 and operated until 1876 on ore mined at Iron Mountain. This operation was economically unsuccessful. Except for the mining and shipment of fluxing ore for non-ferrous metal smelters, no further development work was done until the 1920's.

Near the turn of the century a considerable amount of exploratory work was done on all Southern Utah ore bodies by various individuals and firms, and in 1905 an extensive survey of the Pinto-Iron Springs Area was made by the United States Geological Survey.

Emphasis must be placed on the fact that essentially all development work on Utah ore bodies to date has been confined to the Pinto-Iron Springs District. Development of the Iron Springs District was begun in earnest in 1923 by the Columbia Steel Company (now Columbia-Geneva Steel Division of United States Steel Corporation) preparatory to operation of the Iron-ton blast furnace south of Provo, Utah (blown in May 1, 1924). A spur was built into the Iron Springs

area from Lund, Utah, by the Los Angeles and Salt Lake Railroad (Union Pacific). Loading trestles and crushing equipment were installed by the Columbia Steel Company. Tunnels were driven into the Pioche and Vermilion claims on the northeast slopes of Granite Mountain and raises were run to the surface. The ore was then mined and passed through these raises in a modified glory-hole system. In 1925, a steam-shovel open-pit operation was commenced at Desert Mound on the west of Granite Mountain. In 1935-1936, open-pit operations were moved to Iron Mountain (Pinto Mining District) and in 1937 some vein mining was commenced on the south slopes of the Three Peaks (Iron Springs Mining District) for open-hearth ore. World War II, with its expansion of the western iron and steel industry of which the construction and operation of the Geneva Plant was a part, saw a large increase in mining and development of the ore bodies, principally those on Iron Mountain.

The growth of the district can readily be seen by a study of Table 6—VII, which gives statistics of tonnages of iron ore mined in Iron County from 1923 to 1953.

At present the major portion of the ore mined in Utah is mined by the open-pit method with electric shovels. Transportation is by truck from shovel to crusher, and by railroad from crusher to the consuming plants.

Common practice is to crush ore to a top size within

the range of 1 inch to 1¼ inches. The crushed ore at the Geneva plant is blended to uniform composition by bedding with the use of stackers. It is then reclaimed from the beds, screened into two sizes, a coarse product (plus ¼-inch) and a fine product (minus ¼-inch). The fines are then sintered to form a coarser product (plus ¼-inch) which is proportioned with the original coarse fraction of the ore for use in the blast furnace.

Ore Reserves of Utah—Bureau of Mines data as to reserves of iron ore in Utah are summarized in Table 6—VIII. Of the ore reserves presently known, it is felt unofficially by various observers that approximately 200,000,000 long tons are so situated and of such composition as to be commercially mineable.

SECTION 6

THE LAKE SUPERIOR DISTRICT

Location—The great iron-mining region known as the Lake Superior District is part of the southern border of a vast area of Pre-Cambrian rocks geologically termed the Canadian Shield. The district includes several separate mining centers or ranges, as they are

called, some of which lie within the United States, and others in Canada (Figure 6—6). Among the Canadian ranges, which are found in the southern part of the Province of Ontario, are the Michipicoten, Gunflint, Atikokan, Animikie, and Kaministiquia. Those occur-

FIG. 6—6. Map showing location of iron-ore ranges, Lake Superior district, and of upper and lower lake ports.

ring in the United States are six in number, including the Cuyuna, Mesabi, and Vermilion in Northern Minnesota, the Penokee-Gogebic in Northern Wisconsin and western part of the Upper Peninsula of Michigan, and the Menominee and Marquette ranges of Northern Michigan.

Importance—The Lake Superior District, the greatest iron-mining region in the world, started production of ore in the year 1854, the first shipments coming from the Marquette Range in that year. To 1954, the Lake Superior district had shipped a total of 2,931,690,134 tons, the maximum during any one year being 99,033,748 tons in 1953.

General Geology—Geologically, this area is one of great complexity and is composed principally of rocks of Pre-Cambrian Age, numbered among which are some of the oldest known geological formations. The Lake Superior District lies within what is termed in geology a geosyncline, that is, a great basin-shaped depression or fold within which occur many minor folded areas or basins, the latter being the location of many of the iron ranges.

The rock formations found in this district include all types—igneous, metamorphic, and sedimentary—but the iron-ore deposits are found chiefly in the sedimentary strata occurring in what are called "iron formations." The latter term includes rocks comprised of banded ferruginous cherts, jaspers, slates, graywackes, and conglomerates which are components of the Archean and Huronian series of this great Pre-Cambrian mass. Besides the Pre-Cambrian rocks, some isolated areas of Cambro-Ordovician limestones and sandstones occur within the district and on the Mesabi Range local patches of Cretaceous sediments are also found. The region has been heavily glaciated and a thick mantle of glacial detritus covers a considerable portion of the area, making outcrops scarce, so that on many of the ranges the ore has been found only by dip-needle surveys and diamond drilling. A more detailed account of each of the ranges, together with some of the geological facts concerning the association, occurrence, and origin of the iron ores, follows.

The Marquette Range—This range is located in the northern part of the Upper Peninsula of Michigan. It covers an area about 30 miles long and 6 miles wide striking in an almost east-west direction, and includes from east to west the towns of Negaunee, Ishpeming, Palmer, Humboldt, Republic, and Michigamme. However, the towns of Ishpeming and Negaunee are the center of the main iron ore producing area. This range is the oldest of all the United States ranges in the Lake Superior District, the first ore being shipped in 1854, and it is still active. From its initial production to 1954, it had yielded 273,365,217 tons, while its greatest annual output was 6,540,731 tons in the year 1942. The ore on this range is extracted principally by underground-mining methods, but, in the vicinity of Palmer, some mining by open-pit methods is employed.

Hard and soft hematites comprise most of the ores mined on the Marquette Range, though some limonite and magnetic varieties are also found, splendid masses of needle limonite being common, especially in vugs in the soft hematite ores. The ores are of hard and soft varieties and are blue, red, brown, and yellow in color. The hard ores are blue, the other colors being common to the softer grades. The texture of the ores also varies, some being fine-grained or massive, some porous, some conglomeratic, and others micaceous in character. Both bessemer and non-bessemer types are mined, though high-silica ores are also produced, especially at Palmer and Michigamme.

The deposits occur in what might be termed four horizons which are included in three geological formations, all of which are Upper Huronian in age. These horizons, the geological formations in which they occur, and the ores derived from them are indicated in Table 6—IX.

Table 6—IX. Geological and Mineralogical Features of the Marquette Range.

Ore Horizon		Geological Formation	Derivative Ores
Basal Portion.		Michigamme Slates	Soft red and yellow hematites and limonites.
Top of Series	Conglomerate at base, lying at contact with Negaunee.	Goodrich Quartzite	Hard blue and red hematite and martite ores.
Bottom of Series	1. Top of formation at or slightly below contact with Goodrich Quartzite.	Negaunee Iron Formation	1. Hard, massive, and micaceous, blue and red hematite at or near contact. Soft red and yellow hematite and limonite lower.
	2. Bottom of formation.		2. Soft red, brown, and yellow hematites and limonites.

The major part of the ore produced on the Marquette Range comes from the Negaunee Iron Formation. The conglomerate ores of the Goodrich quartzite consist of a rather thin fragmental layer, while the ores in the Michigamme slates are found in comparatively small lenses or belts of iron formation surrounded by slates.

The Negaunee Iron Formation is now believed to be correlated with the Biwabik, Ironwood, Vulcan, and Deerwood series of the other ranges here described as occurring in the Lake Superior District. It consists of banded ferruginous, carbonate, and siliceous cherts, and slates, together with quartz, actinolite, magnetite schists and massive and banded jaspers. The jasper phases are the most characteristic rocks associated with the hard ore. The jaspers are found in the top portion of the Negaunee, the cherts are in both top and bottom, while the slaty and schistose phases lie between. The whole formation has a thickness well over 1,000 feet, possibly being 2,000 feet thick, though the latter figure may include beds which have been repeated by folding.

Underlying the Negaunee is a series of gray and greenish-gray graywackes, and slates, known as the Siamo slates. Directly overlying the Negaunee, unconformably, is a quartzite and arkose series called the Goodrich quartzite. At the base of this latter formation locally occurs a coarse conglomerate containing, among other materials, iron formation and ore fragments. This conglomerate is the horizon of the hard blue conglomeratic ores.

Still higher in the geological scale and overlying the Goodrich is the Bijiki schist, a quartz-magnetite-grunerite (amphibole) schist, while overlying this formation is a thick slate series (the Michigamme) containing ferruginous, graphitic, and carbonate slates with local lenses and belts of banded chert. In these cherty portions the soft brown, yellow, and red hematite and limonite ores occur.

Besides the sedimentary formations above enumerated, both acidic and basic intrusives are found on this range. These consist of dikes, sills, and stocks of diabase, diorite, and some quartz porphyry.

Structurally, the Marquette Range is very complicated, due to excessive folding and the presence of numerous igneous intrusives. Faulting is also present locally. Taken as a whole, the range represents a gently westward pitching synclinalorium, or trough, containing many minor folds within its limits, the latter of which have approximately the same pitch as the major syncline. Locally, as at Republic, where the strike and pitch are northward, these minor folds vary from the general structure of the range. Part of this folding is due to earth movements, while some is due to pressures caused by the igneous intrusives. The ore bodies occur as irregularly shaped shoots or lenses generally found in the following structural locations:

1. Occupying synclinal folds in the Michigamme Slates or Negaunee Iron Formation.
2. In the bottom of troughs formed by the intersection of the Negaunee and the diabase and diorite dikes and sills.
3. Along the contact between the Negaunee Iron Formation and Goodrich Quartzite.
4. Along the contact between the Negaunee Iron Formation and the Siamo Slates.
5. Within the Negaunee Iron Formation itself.

Where the concentration occurs in closely folded areas, the deposits are generally steeply dipping and pitching, whereas in the shallower folds and troughs, the dip and pitch is flatter; of these two types, the former is more commonly found.

The ores of the Marquette Range were formed during at least two periods of concentration, the hard ores antedating the soft ores. Their origin has been described as due to downward percolating ground waters, but evidence is at hand which suggests that the hard ores at least may be connected with the presence of hot waters and gases accompanying some of the intrusives found in the district.

The Menominee Range—This range, as a whole, includes five mining districts located in Northern Wisconsin and the southeastern part of the Upper Peninsula of Michigan. These five districts are the Iron River, Crystal Falls, Felch Mountain, and Menominee in Michigan, and the Florence District in Wisconsin, the total area of all being 54 miles in length and 15 miles in width. The Menominee and Iron River-Crystal Falls areas are the only ones now operating, the first extending from the town of Iron Mountain on the west to Waucedah on the east, while the other two are centered around the town of Iron River and Crystal Falls, respectively. The discovery of iron ore on the Menominee Range dates from 1873, but actual shipments began in 1877 and have been continuous ever since. The total shipment up to 1954 had amounted to 244,059,350 tons and the largest shipment, that for the year 1916, was 6,562,106 tons, 1926 being next with 5,946,377 tons.

For convenience, it is best to consider the Menominee District separate from those of Iron River and Crystal Falls, since their ores are of different character and are

found in two different geologic horizons. The Menominee District ores are generally blue and reddish-brown soft, porous and lumpy hematites, often high in lime and magnesia. The gangue minerals are quartz, calcite, dolomite, pyrite, and chlorite. Both bessemer and non-bessemer grades are obtained, as well as some ores of siliceous and manganiferous character. The ores of the Iron River-Crystal Falls vicinity contain hematite and the hydrated oxides of iron, such as limonite. They are blue, red, and brown in color and are also soft, porous, and lumpy. The gangue minerals here are much the same as in the Menominee District, except that gypsum is rather abundant locally. Manganiferous ores are also produced from some of the mines in this district.

All the deposits on the Menominee Range occur in sedimentary formations of Upper Huronian Age, but in two different horizons. Those of the Menominee District are in what is known as the Vulcan Iron Formation, while the ores of the Iron River-Crystal Falls, and Florence Districts are found in the basal portion of a thick slate series locally termed the Michigamme slates. The Vulcan Iron Formation is from 600 feet to 800 feet thick and consists of banded ferruginous, carbonate, and siliceous cherts and slates. It is divided into four members, which from top to bottom, are:

Formation	Average Thickness
Curry Chert or Jasper.....	150 feet
Brier Slates	300 feet
Traders Chert or Jasper.....	125 feet
Traders Talc Slate and Quartzite	75 feet

The Vulcan series is underlain by quartzite about 70 feet thick and a siliceous dolomite known as the Randville, the latter belonging to the Lower Huronian. It is overlain by the Michigamme, or Hanbury, slates, a ferruginous, siliceous and carbonaceous graywacke, slate and quartzite series which, in other parts of the range, also contain belts or lenses of banded cherts productive of iron ore. In the Menominee District the ores occur in the Traders jasper and Curry jasper members of the Vulcan Iron Formation, most of the production coming from the Traders. The footwall is generally the Talc slate where the ore is in the Traders with a hanging wall of Brier slate. Where the ore occurs in the Curry member, Brier slate may be the footwall and Hanbury slate the hanging wall. In some instances, the ore bodies lie entirely within the jasper.

The deposits of the Iron River-Crystal Falls Region lie in the basal part (the lower 400-500 feet) of the Michigamme slates. They are found in banded, ferruginous and carbonate cherts occurring as lenses in the slates. Generally, either the foot or hanging wall is a black graphitic and pyritic slate, but siliceous slates, graywackes and even iron formation sometimes form the enclosing walls. In some instances greenstone volcanics (the Hemlock series) form the footwall. Basic intrusives also have been encountered locally.

Structurally, both the Menominee and Iron River-Crystal Falls areas are complicated by drag folding and faulting, close folding being especially predominant in Iron River and Crystal Falls, while faulting is more pronounced on the Menominee. As a result, most all of the ore bodies on this range are steeply dipping (from 45° to 90°) and have a definite pitch, especially where they occupy the troughs of pitching folds. Throughout the whole range the ore deposits are generally found in irregularly shaped lenses or shoots, sometimes reaching 250 feet in width and as much as 1600 feet in length. As a rule, they are found in one of five locations, namely: along a slate-jasper contact;

along a fault or at the junction of faults; in the bottom of V-shaped dragfolds; within the chert or jasper member itself; in locations containing a combination of these factors.

The ores are supposed to have been concentrated by ground waters circulating downward along the faults or bottom of folds, or along the slate-jasper contacts, leaching the silica from the cherts, adding oxides of iron partially through oxidation and partially by replacement, besides concentrating the hematite already present.

The Gogebic Range—This range is situated in Northern Wisconsin and the western end of the Upper Peninsula of Michigan. In all, it is about 80 miles in length, strikes almost east and west, and includes the towns of Mellon and Hurley, Wisconsin, and Ironwood, Bessemer and Wakefield, Michigan. The district was first opened in 1884, and to 1954 had shipped 288,297,060 tons of ore, shipping in 1929, 7,624,085 tons.

The ores are, for the most part, soft, greasy, red hematite with minor amounts of limonite. There are also some hard blue ores as well as local areas high in manganese content.

The iron formation, locally called the Ironwood series, is Upper Huronian in age and is equivalent to the Biwabik formation of the Mesabi Range. It consists of banded ferruginous and carbonate cherts and slates having a total thickness of 600 to 900 feet, and is divided into five members known from top to bottom as:

Formation	Average Thickness
Anvil Cherts	130 feet
Pence Slates	85 feet
Norrie Cherts	125 feet
Yale Slates	140 feet
Plymouth Quartzite, Slate and Cherts....	150 feet

All of these members yield ore in one place or another, but the cherty members are the most consistently producing ones. On the western end of the range, from just east of the town of Upson westward, the character of the Ironwood formation changes and the cherts become recrystallized into finely-crystalline quartz, actinolite, magnetite rocks. This change in character of the iron

formation may be due to the influence of igneous intrusives nearby.

Underlying the Ironwood series is what is known as the Palms quartzite and quartz slates, while overlying the iron formation is the Pabst fragmental (conglomerate) and Tyler slates of Upper Huronian Age.

Over most of the range, the structure is simple, all of these sediments dipping to the north at from 60° to 70° angles. Only at the eastern and western ends is any great complexity encountered, and this is mainly in the form of drag folding, although at the eastern end intrusives also are found. However, faulting is met in most of the mines, and this occurs both transverse to and along the strike of the formation, one major strike fault in the Yale slate horizon extending for many miles along the range.

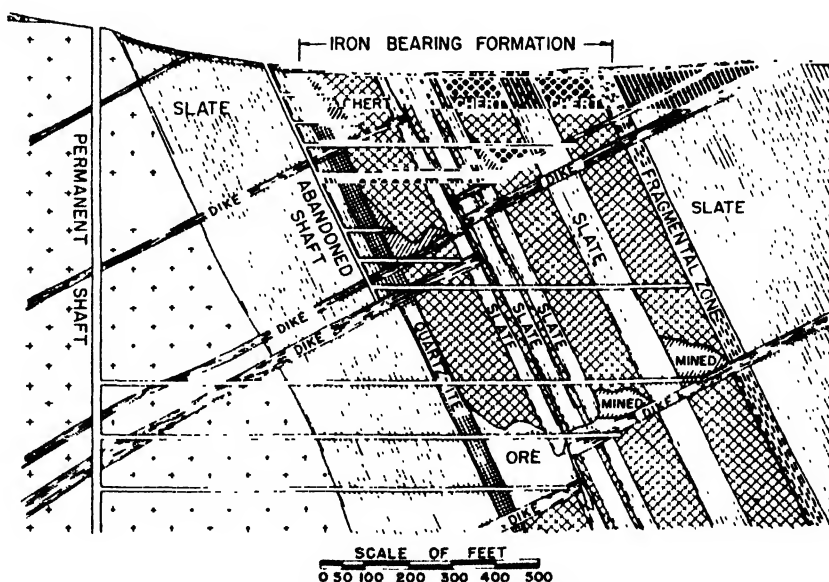

A further geologic feature of importance is the large number of basic dikes (diabase, basalt) which cut the iron formation in numerous places (Figure 6-7). These dikes are of Keweenaw Age. They are found in various thicknesses and generally have a south dip so that their intersection with the iron formation forms a V-shaped trough. These troughs are the location of most of the ore concentration, the pitch of the ore bodies being determined by the pitch of the dikes which, on the Gogebic, is generally eastward, though some westward pitching dikes also occur.

The ore bodies occur as irregular or lenticular-shaped shoots which occupy the troughs of the dike-iron formation intersection, pitching in the direction of the pitch of the dike. In some instances, however, ore has been found at the Palms quartzite (footwall) and Pabst fragmental (hanging wall) contacts with the iron formation, irrespective of dike intrusives.

The origin of these ores has been ascribed to downward-percolating ground waters causing the leaching of the silica and oxidation of the carbonates of the cherts and slates with the resultant concentration of iron oxides into ore as it is now found. These ground waters are assumed to have followed down from the surface along the V-shaped troughs on the impervious basement formed by the dikes penetrating the more or less porous cherts, leaching the silica and enriching the formations in iron oxide to form ore.

The Vermilion Range—This Minnesota range lies

FIG. 6-7. Diagram illustrating cross-section of Gogebic iron-ore range.

about 100 miles north of Duluth. It is about 30 miles in length, striking in a northeast-southwest direction, with the towns of Tower on its southwest and Ely on its northeast end. The district first started producing in 1884 and contains the oldest mine in Minnesota, the Soudan, which began operations in that year. Up to 1954, 89,530,403 tons of ore had been shipped, the largest shipment being 2,084,263 tons in 1902, while the shipment for 1953 was 1,613,155 tons.

The ores consist of blue and red hematite, largely very hard and massive, but in the eastern end of the range at Ely a great part of the ore is soft and porous. The chief gangue minerals are quartz, chlorite, pyrite, calcite, aragonite, and siderite, the carbonates being rarer than the other minerals. Native copper and copper sulphides are also found in some of the area.

The iron formation, known as the Soudan, is Archean in age. It consists of belts and disconnected lenses of massive and banded jasper, which occur in an earlier greenstone complex. The jasper is composed of recrystallized chert (now quartz), interlaminated with iron oxides in the form of both hematite and magnetite, and at times also contains amphiboles. Outcrops are scarce, since the region is more or less heavily covered with glacial detritus. The greenstone complex, known as the Ely greenstone, comprises chloritic and sericitic schists, the altered equivalents of former basic lava flows, tuffs and volcanics. Some black carbonaceous slates are also locally encountered in this formation. The Ely greenstone is also Archean in age.

The whole district is one of great geological complexity, for the two formations described above are in turn cut by numerous basic and acidic intrusives in the form of basalt, diabase and quartz porphyry dikes and sills, all of which are of Pre-Cambrian time. Besides the complications due to these igneous intrusives, the rocks are also intensely folded, often in three planes, so that the narrow belts of iron formation are now found in a steeply dipping position. Faulting is also present, being both postmineral and premineral in age.

The ores on this range lie entirely within the Soudan formation with enclosing walls of greenstone or sericitic schist. It is readily seen that with the complex geology here present, the ore bodies would probably be of irregular shape, and such is the case. They occur as irregular and podlike shoots with a steep dip and pitch, sometimes occupying the trough of folds and are generally less than 200 feet in width, though this width is exceeded where the iron formation has been repeated on itself by folding.

In this district, the deposits have resulted through the leaching of the silica in the jasper, leaving the hematite in more concentrated form. They have been further enriched through the addition of hematite from outside sources. The factors, which have been instrumental in bringing about this leaching and enrichment, have been ascribed by some to downward-circulating water following the contact between the jasper and the greenstone. However, from later studies made, there is also abundant evidence that hot ascending gases and waters, which accompanied or followed the intrusives so commonly found associated with the ores, may also have been instrumental in their concentration.

The Mesabi Range—The Mesabi Range (formerly spelled Missabe) of Minnesota comprises a belt of iron formation 120 miles in length, with a strike of about N. 70° E., and is located at distances varying from 60 to 120 miles W., N.W., and N. of the city of Duluth. It includes the towns of Grand Rapids, Coleraine, Hibbing, Chisholm, Buhl, Virginia, Eveleth, Biwabik, and Aurora, and contains the greatest open-pit mining op-

erations in the world. This range was first opened in 1892. Up to 1955, it had shipped 1,973,000,000 tons of ore, and in 1953, the year of its greatest production, over 75,000,000 tons were shipped. Several mines or open pits in this region have yielded over 1,000,000 tons annually, and one, the Hull-Rust Group, in 1942, shipped an unsurpassed total of 21,401,123 tons. During the war years, 1941-1944, inclusive, 76,267,731 tons were shipped from this one mine.

The ores mined on the Mesabi Range are mainly soft, porous blue, red, yellow and brown hematites, with minor amounts of magnetite, and some of the hydrated oxides of iron. They are of both Bessemer and non-Bessemer grades. Some siliceous ores are also produced, and others are concentrated before shipping by screening, crushing and washing. The Mesabi ores are mined principally by open-pit or quarrying methods, but in some localities where the ore is overlain by great thicknesses of glacial overburden and rock, underground-mining methods, such as top-slicing and caving systems, are employed.

The Mesabi deposits occur in what is known as the Biwabik Iron Formation, which is Upper Huronian in age. This formation consists of a series of banded ferruginous cherts, slates, graywackes, and conglomerates. The total thickness of this formation, to which has been applied the generic term "taconite," ranges from 400-750 feet. Besides the oxides of iron, the chert contains carbonates and several iron silicates. It is characterized by many different phases, some being sugary, some granular, while other types show oölitic and algal structures. The Biwabik series has been divided into four members, each of which is recognizable in the field and characterized by the ores which it produces. These divisions, from top to bottom, as well as the ores derived from them, are listed as follows:

Formation	Thickness (Feet)	Derivative Ores
Upper Slaty	0-100	"Paint Rock" Ores
Upper Cherty	175-200	Blue and Brown Ores
Lower Slaty	60-220	{ Fine Blue and Yellow Ores, Paint Rock at base
Lower Cherty	60-250	{ Yellow Ores—Top Blue Ores—Middle Brown Ores—Base

Overlying the iron formation conformably is a thick slate series, the Virginia slates, also of Upper Huronian Age, while underlying is a vitreous quartzite known as the Pokegama.

While the character of the iron formation is fairly uniform over most of the range, it shows a distinct change at its eastern end, where it has been altered by a great gabbro intrusive (the Duluth laccolith) into a series of quartz, amphibole magnetite schists and slates.

The geologic structure of the formations of the Mesabi Range is fairly simple. They are practically flat-lying, having only a shallow 10° dip to the south. As the ore has been formed chiefly through the leaching of the silica content of the cherts, and some oxidation of the carbonates and silicates of iron, the formations in the ore areas are more or less porous. In this case, the weight of the overlying rocks causes slumping in the ore areas with a down-dropping of the layers in which concentration has taken place (Figure 6-8). Local folding and faulting is encountered in some of the mines, but for the most part, the folding is shallow and gentle and not in any way as intense as on the other ranges of

Fig. 6-8. Typical cross-section of Mesabi Range ore body.

the Lake Superior District. One large drag fold of great magnitude occurs in the vicinity of Eveleth and Virginia, causing the eastern extension of the range to be thrown to the south. This is termed "the horn," the mines of Virginia lying in its synclinal portion, while those of Eveleth are on the anticline.

The shapes of the ore bodies are of three types; namely, (1) Those occurring in shallow folds or troughs; (2) The fissure type; (3) The flat-lying or bedded ore body. The trough ore body generally owes its location to a broad shallow fold. The fissure type is smaller than the trough ore bodies and has resulted from the leaching of the iron formation and concentration of the hematite along sets of joints or fracture planes. The flat-lying ore bodies are wide and generally shallow, concentration being extensive and fairly uniform through the deposit. These three types of ore bodies often grade into one another and one may contain representatives of the other two. The concentration here, as on most of the other ranges, has probably been caused by downward-circulating ground waters.

Shipments of the depleting natural ores of the Mesabi Range will gradually be replaced by rich iron-bearing materials resulting from the beneficiation of taconite. Processes for beneficiating taconite are passing from the experimental stage into large-scale commercial operation. The term "taconite" embraces a wide variety of iron-bearing rocks (containing an average of about 30 per cent iron) found in the Lake Superior District. At the present time, commercial operations on the Mesabi Range have been restricted to the variety of taconite in which a major proportion of the iron is present as the mineral magnetite, which can be separated from the gangue by low-intensity magnetic separation. In the other types of taconite, most of the iron is present in such non-magnetic minerals as martite, hematite, iron silicates and iron carbonates. Of these types, those containing hematite and martite are the predominant iron minerals (when the minerals have a sufficiently coarse grain size) constitute a reserve of material amenable to concentration processes. The concentration of the non-magnetic minerals requires processes more complex than those required for magnetite. The taconites containing magnetite comprise the bulk of iron formation on the eastern portion of the Mesabi iron range, but very little of this kind is found in the western portion where hematite and martite are the principal iron minerals. Potential reserves of several billion tons of commercially-usable taconite are available on the Mesabi Range.

The Cuyuna Range—This is the most-recently opened of all the iron ranges in the United States portion of the Lake Superior District. It is located in Crow Wing County, Minnesota, the principal towns in the area being Deerwood, Crosby, and Brainerd. The strike of this range is in a northeast-southwest direction, more or less similar to that of the Mesabi, lying to the northeast of it. The late discovery of the deposits in this region is due, in a great degree, to the lack of outcrops, since the area is heavily covered with glacial drift. Most of the ore bodies have been disclosed by careful magnetic (dip-needle) surveys and diamond drilling. The Cuyuna was first opened in the year 1911, and to 1954 had shipped 80,264,536 tons of ore, the largest shipment being 3,714,684 tons in 1953.

The ores here are red, yellow, and brown hematite and limonite, the blue varieties being less common. As a rule, they are soft, porous, and fine grained. Some are high in phosphorus, others siliceous. Manganese occurs rather abundantly on this range, being over 15 per cent in some locations.

The ore bodies are generally irregular and lenticular in shape with a rather steep dip and pitch, often having basic intrusive rocks as a footwall. The deposits occur in two geological formations, both of which are of Upper Huronian Age. These are the Virginia Slate series and the Deerwood Iron Formation which underlies them, the latter in turn resting upon a siliceous slate and quartzite formation known as the Pokegama. The Deerwood Iron Formation is from 1000-1200 feet in thickness, and consists of banded ferruginous and manganiferous cherts, slates, graywackes, and quartzites, and can be divided into four horizons similar to those occurring in the Mesabi Range. Intrusive and extrusive rocks of both basic and acidic character are common in the region, while close folding and faulting also add to the complexity of the geological structure.

The Virginia slates yield the brown ores of what is locally termed the South Range of the Cuyuna, these being narrower than those of the North Range, which are found in the Deerwood formation and, in places, attain a thickness of 500 feet, the ores being red, blue, and brown hematite and manganiferous types. Little work has been done in the investigation of the origin of the Cuyuna ores, but from what has thus far been done, their occurrence and concentration are believed to be due to the same agencies which formed those of the Mesabi Range, viz., leaching of the silica and concentration of iron and manganese by downward circulating surface waters.

SECTION 7

MINING THE LAKE ORES

Prospecting and Exploration—Since the Lake Superior ores occur in pockets or distinct bodies and vary much as to character and location, the actual mining of the ores is preceded by much work of an exploratory character. This work includes prospecting and exploration.

Prospecting is the term generally applied to the quest for surface indications of ore, or the conditions which would warrant the expectation of finding ore in the vicinity. It includes such quest operations as geological examination, dip-needle work, shallow test-pitting, and trenching. The ore bodies of the Mesabi Range are slightly magnetic, and the Magnetometer or Hotchkiss super-dip needle sometimes are of use in outlining areas for drilling. On the Cuyuna Range, magnetic attraction, as evidenced by the dip needle, has been extensively employed as a guide to the location of ore deposits; in other localities also the dip needle has found limited application.

Drill Exploration—After the presence of an ore deposit is known or suspected, resort is generally had to exploration by means of diamond or churn drills. On the old ranges, geological conditions generally make this manner of ascertaining the exact limits of an ore deposit impracticable; so, if two or three adjacent drill holes develop considerable depths of ore, the sinking of a shaft for underground exploration, development and mining is generally considered warranted. On the Mesabi Range, however, the flat-lying and comparatively shallow characteristics of the ore formation warrant much more extensive drill explorations. On this range, then, an ore body is almost invariably followed out with the drills, and its limits are determined to the point where the complete plan of development can be worked out in advance of actual mining operations.

Methods of Mining—Both open pit and underground methods of mining are employed in the mines of the Lake Superior District. On the old ranges, where the ore bodies often extend to great depths and usually lie at angles so steeply inclined to the horizontal that the surface exposures, or outcrops, are small, underground-mining methods are employed almost without exception. On the Mesabi Range, the ore bodies are, as a rule, flat-lying with relatively large areas of outcrop, and open-pit mining is, therefore, general. Of course, there are a few deposits on this range that, on account of limited operating area, excessive depth of overburden, or for other reasons, must be mined by underground methods. But by far, the greater part of the tonnage produced from the Mesabi Range comes from open pits.

The mining of taconite poses problems because of its extreme hardness, requiring considerable additional drilling and blasting, and, because of the adverse concentration ratio, requires the handling of tremendous quantities of material.

OPEN-PIT MINING

Before deciding whether an ore body should be mined by underground methods or as an open pit, a detailed operating analysis is made of the property to determine by which method the ore can be mined most economically. Estimates are made determining the yardage of overburden, or "stripping," that must be removed to uncover the ore body, the tonnage of ore which can then be mined by power shovels and the additional

tonnage which can be "scrammed" in the pit after the limits of shovel operation have been reached. Then the cost of the entire operation, including interest charges on the necessarily large investment in stripping removal, is calculated and reduced to a final cost per ton of ore recoverable. If this figure is less than the probable cost per ton of underground mining, and if the other operating conditions are satisfactory, open-pit operation is, of course, deemed advisable. If mining by open pit methods is indicated, a decision must be made as to whether rail, truck, or belt-conveyor haulage is to be used. The planning of an open-pit mine involves the following engineering problems; first, outlining the area of ore which it will pay to strip, i.e., considering the two factors of depth of ore and thickness of overburden; second, planning the disposal of stripping which it will be necessary to remove to uncover the ore body, for this material must often be hauled considerable distances from the pits to dump grounds; third, locating the haulage systems outside the pit for the transportation of waste material and ore; fourth, designing the system of railroad tracks or roadways within the pit that will make available the maximum quantity of ore accessible by power shovels, which designing generally involves a series of switchbacks on limiting operative grades and curvature; fifth, providing for draining of the pit; and sixth, planning in advance for the mining of the ore that cannot be mined by power shovels.

Haulage Systems—Three haulage systems are utilized in open-pit mining on the Mesabi Range; i.e., railway, truck and belt conveyor. The haulage system employed is dependent upon the shape of the ore body, the quantities of stripping and ore to be moved, length of haul necessary to dispose of waste material and to deliver the ore to the beneficiation plant, and the equipment available. A rail haulage system is generally restricted to track grades of 3 per cent or less and from 12° to 16° curves, and its use is, therefore, generally limited to large, regularly shaped ore bodies. Truck haulage systems are more flexible than rail systems, and can be adapted to deep, irregularly shaped ore bodies. Road grades of 8 per cent are common in "truck pits" and steeper grades can be employed over short distances.

Removal of dirt stripping and ore from open-pit mines by belt conveyors is often the most economical and convenient means of transportation. It is well adapted to comparatively small, deep ore bodies with a limited area for the operation of power shovels and to larger open pits where conditions are suitable. Belt-conveyor systems can be either underground or surface installations. In an underground installation, an inclined belt-conveyor drift is driven from a location on the surface, where railroad facilities are available, to a carefully selected location as near as possible to the lowest elevation and center of the open-pit ore body. A shaft is driven from the top of the exposed ore in the pit to the lower end of the conveyor drift. Trucks are used for gathering the ore to a truck station or pocket at the collar of the shaft from where the ore is dumped through the shaft to the lower end of the conveyor unit. As mining and consequent deepening of the pit progresses, the collar of the shaft and truck station are lowered. In a surface installation, ore haulage is accomplished in the same manner as an underground

FIG. 6-9. Open-pit iron-ore mining.

installation, but the belt conveyors and truck station are installed on the surface of the pit profile and no shaft is necessary. As the ore is mined, the truck station is lowered and the belt conveyor is extended down to the new elevation of the pit bottom. A modification of that system is often used wherein the truck station is permanently installed at the bottom of the overburden near the edge of the ore body, with the ore hauled by trucks up to the truck station and by belt conveyor from that point to the railroad facilities on the surface.

Drilling and Blasting—The banks ahead of the power shovels, in preparation for loading, are shaken and loosened by blasting. To accomplish this, horizontal holes are sometimes drilled at the foot of the bank, but the common practice is to use vertical holes. These holes are drilled by mobile, self-contained units of the well-drilling type and are equipped with either electric, gasoline, or Diesel power. The holes are 6 to 9 inches in diameter and as deep as the height of bank desired. This type of drilling has the distinct advantage of column loading for blasting purposes, obviating the necessity of chambering the hole by springing prior to loading.

Waste Dumps—Waste dumps are located on barren ground, often at some distance from the open pits. Sites are selected for their accessibility and for quantity of material to be stored with minimum grades to secure desired results. Should the surface be nearly level, dumps for rail haul are started by building a grade fill, often twenty to thirty feet high, using trucks and power shovels. Tracks are then laid on this grade fill and, after the dump is established in this manner, the tracks can be fanned out to the right and left. When a dump track is completely filled, a spreader plow is used to level the dirt, following which the track is moved over by a machine known as a track-shifter. With use of trucks, advantage of rise in elevation of ground is usually sought to start a dump. However, if necessary, the approach to the dump can be built up by successive dumping on the roadway until the desired elevation is gained. Equipment such as described above makes it possible to dispose of vast quantities of waste material at low cost.

Scramming—This is a term applied colloquially on the Mesabi Range to the operation of recovering shallow pockets and hummocks of ore left unmined in and around the open pits following the period of power shovel mining. It is a general term inclusive of hand work, scraper work, mining with dragline excavators, bull-dozers, etc., and is applicable generally to the operation of "cleaning up" a pit after its period of real production has passed.

Drainage—Whenever an open-pit mine is deepened to the point where water interferes with operations, drainage must be supplied. This is accomplished in several ways, such as sinking shafts and driving laterals to intercept the flow of water, or by sinking wells 26 to 32 inches in diameter in which are installed deep-well pumps of sufficient capacity to dispose of the flow of water encountered. This type of pump has the advantage of keeping the motive power on surface while the pump is submerged at any desired depth. All such equipment is electrically operated. These wells or shafts are so located as to extend into the deepest areas of the mine, and at the same time so placed as to cause the least possible interference with mine operations. Frequently, a sump is constructed at the lowest elevation in the pit, and a centrifugal pump is installed on a raft to dewater the mine. All such equipment is electrically operated.

Transporting and Sampling of Ores—Aside from mer-

chantable ore, all material removed in open-pit mining is stored in waste or other dumps, as conditions may require. The physical properties of the ore are usually such that beneficiation is necessary to produce a desirable ore for furnace use, and it is loaded into steel dump cars and transported to crusher, screening or concentration plants. After beneficiation, the ore is loaded into ore cars, stored in adjacent railroad yards provided for that purpose, and from that point, transported to upper port docks by railroad. Sampling the ore for analytical and grading purposes is usually performed at the time the ore is delivered to railroad yards and built into trains for transportation to the docks. The usual method is to take one sample from units of five cars each. Unusual conditions might require closer sampling or other variations from standard practice. The usual method permits securing results of analyses in time to effect grading of the ore prior to its arrival at upper lake shipping points.

Crushing and Screening Ore—During the loading of ore in the open-pit mines of the Mesabi Range by power shovels, many large pieces of hard and chunky ore are encountered. These large masses must in some way be reduced to such a size that they will not interfere with the ore being quickly discharged from the dock pockets into boats, or be too large for successful blast-furnace operation. Very often large pieces are handled through a shovel dipper into railroad cars entirely unobserved by the workmen, and their presence is first discovered when unloading the hopper-bottom cars at the docks. Here these chunks obstruct the car openings and cause serious delays, and if they leave the cars, they are likely to obstruct the pocket opening.

In order to reduce the size of the lump material several large crushing and screening plants have been constructed. A crusher-screening plant helps to speed up shovel work by making it possible to load all ore, whether chunks or fines, and acts as a mixer to produce a more uniform grade of ore. Before the construction of crushing plants, all large chunks, which did not escape the notice of workmen, had to be reduced by blasting or with hand hammers. Shovels were delayed in picking out these chunks and laying them aside until they could be broken.

The Sherman crushing and screening plant, installed in 1950 with a daily capacity of approximately 50,000 tons of ore, illustrates a typical installation of a plant for crushing and sizing ore.

The plant is composed of two units, each unit having four receiving bins, four double-deck screens and one jaw crusher. The ore is hauled to the plant from the mines in trains of five to ten 30- and 40-cubic yard air-operated side-dump cars. The cars are pushed up a three per cent grade to the top of receiving bins which are 32 feet above the shipping-track grade. The cars are dumped, one at a time, into the receiving bins which have a capacity of 650 tons each (four bins for each crusher). The ore is moved from the bottom of the bins by 72-inch by 27-foot pan feeders which discharge the ore onto 60-inch by 12-foot double-deck vibrating screens. These screens are set in an inclined position. As the ore moves over the vibrating screens, it is separated into three sizes (+5-inch, -5-inch + $\frac{3}{4}$ -inch, and - $\frac{3}{4}$ -inch). The - $\frac{3}{4}$ -inch material goes through both screens and onto a 30-inch belt and is conveyed to a transfer where it goes onto a 36-inch belt running up to the loading pocket. The -5-inch and + $\frac{3}{4}$ -inch material goes through the upper decks of the screens and rolls off the top of the lower deck and onto a 36-inch belt that bypasses the crusher. The +5-inch material rolls over the upper decks of the

screens and goes onto a 72-inch by 70-foot pan feeder and is fed into a 48-inch by 60-inch jaw crusher and crushed to -5-inch size. The +5-inch material can also be rejected by discharging the material from the 72-inch by 70-foot pan feeder onto a 60-inch by 10-foot reversible chain belt that conveys the ore to a 54-inch by 70-foot waste-rock pan feeder. This waste rock is conveyed up and discharged directly into dump cars and hauled to the rock dump. The crushed material joins the -5-inch + $\frac{3}{4}$ -inch material on the 36-inch belt and is conveyed to a transfer where it is carried by another 36-inch belt up to the loading pocket. The two products, coarse (-5-inch + $\frac{3}{4}$ -inch) and fine (- $\frac{3}{4}$ -inch), are loaded separately from the loading pockets into standard-gauge railroad cars for shipment to the docks.

All machinery in the plant is electrically driven, and the capacity is normally limited to the crusher's capacity to handle the chunks. The crusher operators are stationed directly over the crushers with the necessary control equipment to regulate the operations of all conveyors and crusher. A signal system makes it possible for each workman on a unit to know at any time the grade of ore being run, and from what property it came.

OPEN-PIT MINING EQUIPMENT

For the operation of a mine by open-pit methods, the major items of equipment consist of electric- and diesel-powered shovels, diesel-electric locomotives, belt-conveyor systems, trucks of from 15- to 50-ton capacity, tractors equipped with blades, and churn or rotary drills. Other equipment used includes ore and stripping dump cars, flat cars, locomotive cranes, track shifters, spreader plows, automatic tie-tamping machines, tripod and jack-hammer drills, etc.

Shovels—Full-revolving, caterpillar-traction, electric-powered shovels (Figure 6—10) and walking draglines have almost supplanted other types, except in isolated locations where small diesel-powered shovels are generally used. Present shovel and dragline equipment ranges in weight from 90 to 350 tons, and from 2½ to about 10 cubic yard dipper capacity. Dirt, rock and ore banks are drilled and blasted ahead of the shovels to put the material in condition for maximum shovel output. With some of the larger equipment, ore-bank blasting is minimized.

Locomotives—In recent years, 1000- to 1600-h.p., 240-ton diesel-electric locomotives have come into use, supplanting 60- to 125-ton steam locomotives. Tractive effort required for starting loads on heavy grades and length of haul are among the problems in mind when choosing the type of power plant for haulage purposes.

Stripping Cars—Stripping cars are of steel construction, two-way, air-dump, side-hinged type, ranging from 30 to 40 cubic yard capacity, and are used for removing stripping, as well as ore that is to be hauled to beneficiation plants.

Tracks—In providing standard-gauge tracks for open-pit use, the present-day practice is to build up sections on wood ties of one rail length (39-foot standard) at points where track material is stored, making the pit installation as needed by transporting these sections on flat cars, using a locomotive crane for loading as well as laying them in position in the pit. Likewise, as it becomes necessary to move tracks from one point to another in the pit, the same method is followed. Rails used weigh 100 pounds per yard.

Belt Conveyors—Removal of dirt stripping and ore from open-pit mines by belt conveyors is often the most economical and convenient means of transportation. This is becoming increasingly true for ore as the mines

attain greater depths, requiring longer hauls with objectionable grades for locomotives or trucks. The tensile strength of rubber-covered fabric belts has increased in recent years to the extent that they are supplanting similar belts that had required reinforcing by a layer of steel cables placed between the several plies of woven fabric. A 36-inch rubber-coated fabric belt may have a capacity up to 1000 tons per hour. A popular width of belt is 36 inches, speed 500 feet per minute, with about 18° incline.

Electric Power Distribution—Electric power service and distribution for open-pit mines is either at 2400 volts or 4160 volts, 3-phase, 60 cycles. Power shovels and large pumps are operated at these voltages. The present trend is towards 4160 volts, because of the relative increase in mining area which can be economically served.

Shops—The present-day use of large-unit equipment makes imperative the installation of adequate shop facilities adjacent to the operation, such as machine, blacksmith, boiler, electrical, car, truck repair, and carpenter shops. These are provided with modern equipment necessary for the purpose intended.

Safety—In open-pit as well as underground mining, safety is a first consideration. To counteract man failure, as well as that of materials and machines, safety appliances and educational work are both necessary.

Advantages of Open-Pit Mining—It is very apparent that open-pit mining, when feasible, offers decided advantages as compared with underground methods. Probably the most evident of these is the possibility of big production; in 1942, the Hull-Rust Mine alone shipped 21,401,123 tons of ore—more than 20 per cent of the total mined in the United States during that year which, according to the U. S. Geological Survey, amounted to 104,883,184 tons. Where the overburden is light in comparison with the depth of ore, and stripping charges are not heavy, open pit mining produces low-cost ore. It accomplishes a great saving in labor; the output per man per day from the open-pit mine is many times that from the average underground mine.

BENEFICIATION OF ORES

Owing to changes in the character of available ores, most of the tonnage mined must be treated in some way in order to supply the furnaces with ore that can be

Fig. 6-10. Electric power shovel on caterpillar tracks, making a "sinking cut" and loading ore into steel dump cars for haulage from an open-pit mine to a beneficiation plant. Diesel-electric locomotive handles the dump cars. Cable carries power to shovel.

used to best advantage in burdening the furnace. Hard and lumpy ores must be crushed, fines must be agglomerated, rock lumps excluded and lean ores concentrated to a standard iron content. The quantity of beneficiated ores, exclusive of the substantial amounts beneficiated only by crushing or screening, is indicated in Table 6—X.

The flow sheet in Figure 6—11 is typical of a Mesabi

Range concentrating plant using a simple washing process. Additional methods are being used and experimented with for improvement in per cent of iron recovery and cost. These additional methods include heavy-media, jigging, fine grinding, drying, flotation and magnetic concentration. The iron-ore-mining industry in the Lake Superior District is presently involved in the development of improved methods

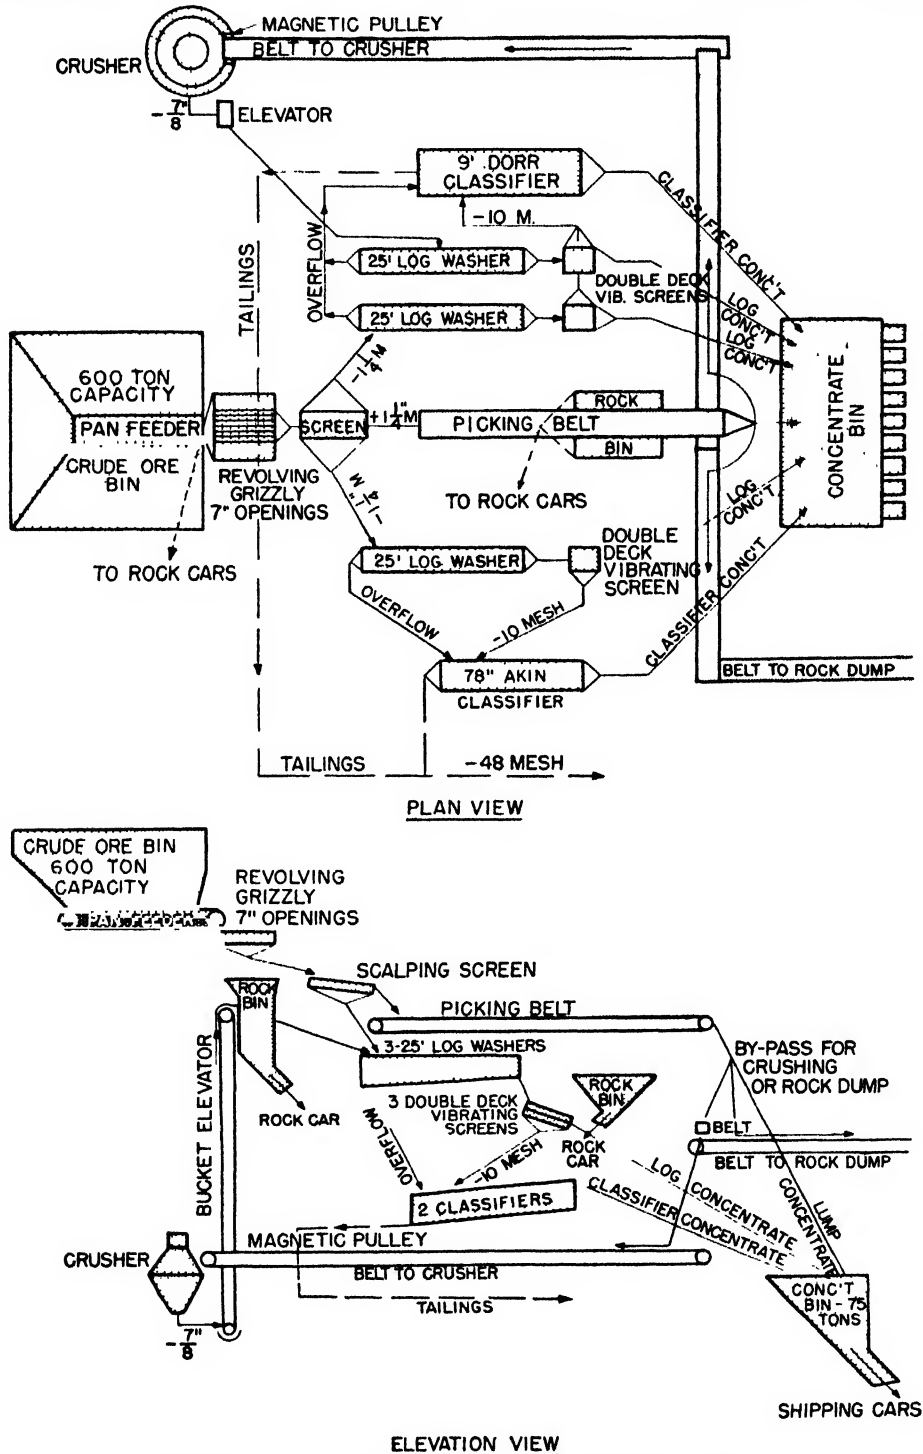

FIG. 6—11. Flow-sheet of a typical Mesabi Range concentrating plant using a simple washing process.

looking to commercial means for the utilization of the low-grade ore and so-called taconite. Taconite, or iron-bearing rock, occurs in immense quantities in the Lake Superior District, and on the Mesabi Range it can be mined or quarried, by open-pit methods.

Processing taconite to produce a usable iron ore requires grinding of the rock finer than 200-mesh to free the iron-oxide particles from the silica and other waste materials. The ore is concentrated by use of magnetic separators which remove the ore particles and reject the silica. These fine iron concentrates must then be agglomerated either by sintering, nodulizing or pelletizing to make a product for furnace use. More than three tons of taconite rock must be processed to produce one ton of usable iron ore. The investment in plant and equipment to produce iron ore from this source is very high. There were three taconite plants in operation on an experimental basis in 1955. These were located at Mountain Iron, Minnesota (Oliver Iron Mining Division, United States Steel Corporation), Aurora, Minnesota (Erie Mining Company), and Babbitt, Minnesota (Reserve Mining Company). There were two commer-

cial-size plants under construction: (1) a 3,750,000 tons per year plant built by Reserve Mining Company at Silver Bay on Lake Superior to grind, concentrate and agglomerate taconite shipped from Babbitt, Minnesota, which started production of iron-ore concentrate pellets for shipment, in October, 1955, and (2) a 7,500,000 tons per year plant scheduled to be in operation by early 1957, being built by Erie Mining Company at Aurora, Minnesota to beneficiate taconite mined in the Aurora

UNDERGROUND MINING

Importance—Underground mining in the Lake Superior Region predominates over open-pit operation on the Michigan ranges and is used exclusively on the Vermilion Range in Minnesota. It is still practiced on a limited scale on the Mesabi and Cuyuna Ranges, but is less important than formerly because long-term cost trends have favored open-pit extraction.

Shafts—In most cases, access to underground mines is obtained through vertical shafts sunk adjacent to the deposit but far enough away to avoid the effects of

FIG. 6-12. Radial top slicing to chutes at a Mesabi Range mine; thick ore body. (From U. S. Bureau of Mines Bulletin No. 390.)

surface subsidence resulting from mining operations. Some inclined shafts are still in use and some ore is removed through adits driven in from open-pit banks. The depth of underground mines varies from as little as 300 feet in the Mesabi District to nearly 4000 feet on the Gogebic. Shafts are divided into several compartments, usually two for hoisting ore in skips (ore conveyances) in balance, one or two for men and materials, and others for ladders, air, water and power lines, and other miscellaneous facilities.

Underground Haulage—On the Mesabi Range, some of the deposits are in the form of thin, gently-dipping beds. In such a situation it is only necessary to establish one main level at or slightly below the elevation of the ore, but in most mines several levels at vertical intervals of from 100 feet to 200 feet are necessary to develop the deposit. On each level, or sometimes only on occasional levels, storage pockets are installed at the shaft for transferring ore from the underground haulage system to the hoisting facilities, and the shaft station is connected with the orebody by a system of haulage drifts. The usual method of moving ore to the shaft is by electric locomotive and tram cars operating on narrow-gauge tracks, but in several instances belt conveyors are in use.

Mining Methods—A variety of mining methods are applied in underground mines of the Lake Superior District, due mainly to the wide range in competence of the ore and enclosing formations and in the dimensions and attitude of the deposits. Cost of mining in relation to the value of the ore is also very important where there is a choice of methods.

Caving Methods—The majority of underground operations are in deposits where the ore and superincumbent rock are too weak to stand unsupported in large openings. Under such conditions, three methods—top-

slicing, sub-level caving, and block-caving—may be applied. In these methods, ore is removed in such a manner that gradual settling of the overlying material is induced, with little or no opportunity for sudden falls of large masses of ground.

In top-slicing, raises are driven vertically from the haulage level to the top of ore at intervals of from 30 to 120 feet for the purpose of transferring broken ore from the working place to the level (Figure 6-12). A timbered room or slice, about 10 feet wide and from 8 to 18 feet high, is advanced on a sub-level directly beneath the rock capping (or broken material resulting from prior operations) from a raise out to the rock walls or predetermined mining limit. Broken ore is drawn by an electrically driven scraper from the face of the slice and dumped down the raise (Figure 6-13). When a slice is completed, it is allowed to cave under the weight of the mass above, or the supporting timbers may be blasted to hasten the process. Succeeding slices are driven, each immediately adjacent to the one preceding in either parallel arrangement or in a radial pattern centering at the raise, until the area tributary to the raise is mined out. This procedure is repeated on successive sub-levels below until the bottom of the deposit is reached. This method also finds application in thin, flat-lying seams on the Mesabi, some of which are only slice-height in thickness. Top-slicing has the advantages of clean ore recovery, high percentage of extraction, and selectivity (important in orebodies highly irregular in outline or badly broken up by waste rock); but is a high-cost method because every ton of ore must be drilled and blasted and large amounts of timber are required. As a result, its use is declining.

Sub-level caving (Figure 6-14) was evolved from top-slicing in order to increase ore-breaking efficiency and decrease timber consumption. It is probably the

most extensively used mining method in the Lake Superior District, particularly on the Gogebic and Vermilion Ranges. In this method the sub-level height is increased to 20 feet or 30 feet, and the width of ore recovered in each slice-block to 20 feet or 30 feet. A timbered drift, about 10 ft. by 10 ft., is driven at the base and on the center line of each successive block. When this opening reaches the rock wall or mining limit, the ore over the back of the drift and on both sides is blasted or caved into the drift in a retreating sequence. One variation of sub-level caving utilizes blocks 50 feet high and 50 feet wide, but requires the use of two bottom scraping drifts plus a third drift above them in order to drill ore in the upper half of the block. Raises for dropping ore from the mining elevation to the haulage level are usually spaced much farther apart than in top-slicing (up to 300 feet) and transfer scraping is necessary to move ore from the slice-drift entrance to the raise (up to 150 feet).

In both sub-level caving and top-slicing, maximum production obtainable is to a considerable extent a function of the horizontal area of the deposit, since within each unit area, the ore on any sub-level must be largely exhausted before extraction can begin on the next one below.

Block caving is a method in which maximum use of the force of gravity is employed to break the ore. It is applicable mainly in clean, massive or tabular deposits which if flat-lying must be at least 50 feet thick, or if steeply dipping must be wide enough in relation to the hardness of the ore to cave or crush readily when undercut. If these prerequisites are not met, other methods will generally prove more economical since they require less preparatory work. In this system, blocks of ore up to 250 feet long and from 50 to 150 feet wide are developed by a series of parallel scraping drifts 25 to 35 feet apart, driven at or near the foot-

wall contact of the orebody or a short distance above the haulage level as the situation requires. The block is undercut at an elevation slightly above the scraping drifts by long holes drilled and blasted either from them or an auxiliary drilling drift located at the undercut elevation. Short, closely spaced **finger raises**, also called **mills**, are put up and "coned" out from the scraping drifts to enable ore caving into the void created by the undercut to be drawn off. Close control of the drawing operation is essential to obtain high recovery of ore with minimum contamination from rock capping or waste from overlying mined-out zones. Recent application of block caving in the Lake Superior District dates only from about 1947 and its current use is mainly on the Marquette Range.

Open-Stoping Methods—In a number of mines, large-sized rooms called **stopes** can be opened up without immediate danger of collapse. In steeply-dipping orebodies having widths of up to 100 feet, the stopes may be arranged so that their long axes coincide with that of the deposit, but in wider orebodies, transverse stopes, separated by vertical columns of ore called **pillars**, are employed. The pillars may be left in place permanently or may be recovered at a later date as dictated by the physical or economic situation. When the walls of the stopes are strong enough to stand unsupported for heights equivalent to the level interval, a method called **sub-level stoping** (Figure 6-15) is commonly employed. In this method one or more scraping drifts, 10 to 25 feet above the haulage level, are driven at the base of the proposed stope. At the same time, sub-level drifts at vertical intervals of 25 feet or more are driven on the stope centerline. From the scraping drifts "mills" are driven to the first sub-level and funnelled out in the shape of an inverted cone. Actual mining is started at one end of the stope by opening a slot across the full width from the first sub-level to

FIG. 6-15. Typical sub-level stoping using scraper system. (From A.I.M.E. Transactions, Vol. 163, "Mining Practice")

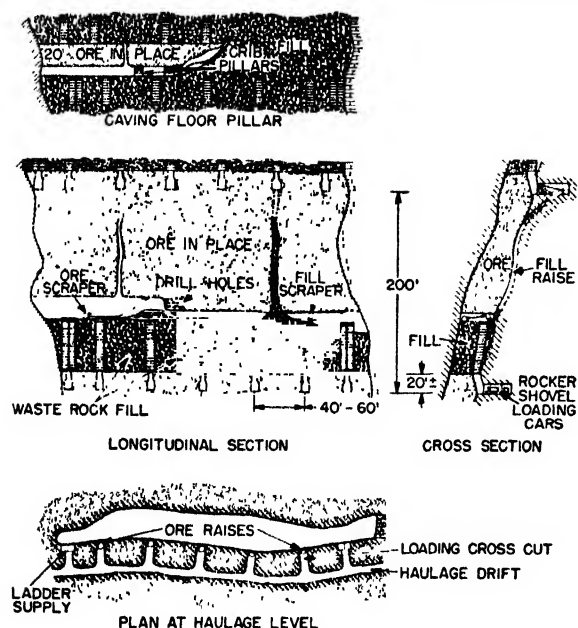

FIG. 6-16. Schematic representation of horizontal cut-and-fill stope.

within 20 or 30 feet of the main level above. Operations are then continued by retreating to the other end of the stope, ore being broken by long holes drilled radially in

vertical planes from the various sub-levels or by shorter holes drilled from benches cut across the working face. Broken ore falls to the bottom of the stope, is drawn through the mills to the scraping drift, where any required secondary breaking is accomplished, and then moved by scraper to a raise leading to the main level. Sub-level stoping is an efficient, low-cost method, and is the most widely used open-stoping system in the region. Its use is particularly widespread in the semi-hard ores of the Iron River and Crystal Falls Districts of the Menominee Range, but has been frequently used in narrow sections of soft orebodies on the Marquette, Gogebic and Cuyuna Ranges.

Several other open-stoping methods are in use where rather unique conditions exist. In each case the ores happen to be quite hard, but other factors have as much to do with the choice of mining method. At one mine, the orebodies are narrow, elongated, and steeply dipping. The rock walls have a tendency to slab off when unsupported for a height of as little as 20 feet. To circumvent this condition, a method called *cut-and-fill stoping* is used (Figure 6-16). The ore is mined between levels 200 feet apart by taking a series of horizontal cuts about 12 feet thick in an ascending sequence. At the completion of each cut waste rock is run into the stope to fill the void left by the removal of the ore. Cribbed chutes are carried upward as filling proceeds so that ore can be dumped down to the haulage level. A somewhat similar system is used at another mine where the deposits have about the same shape with somewhat more competent walls. In this method, called *shrinkage stoping*, broken ore is left in the stope as mining progresses upward. The mill or chute arrangement is

FIG. 6-17. Loading iron ore into steamer.

FIG. 6-18. Unloading ore from boats, showing Hulett electric unloaders in operation, with ore bridges in background.

similar to that used in block caving and sub-level stoping, only enough ore being drawn to offset the expansion in volume due to breaking. The balance is not removed until the stope is completed. At another hard-ore operation, the orebodies are a series of thick, tabular masses originally part of a flat-lying formation but now folded and faulted into numerous segments, dipping at predominantly flat angles. Levels are only 50 feet apart due to the irregularity of the deposit. The total horizontal area to be mined is too great to allow complete removal of the ore so that pillars approximately 25 feet in diameter are left unmined at fairly regular intervals for roof support. The mining system is a combination of methods, the first operation on each level being the opening of rooms about 25 feet high with pillars left as noted above (room-and-pillar stoping). If the ore does not extend to the level above, the back of the stope is mined by drilling from the top of a pile of broken ore (overhand stoping). Where the ore is continuous between levels the floor of each room is broken downward into a central raise leading to the level below (underhand stoping).

GRADING THE ORES

In the early days of iron ore mining, no grading of the ore from composition, such as prevails today, was made, and the ore was known by the name of the mine that produced it. Then, the number of mines was small, and the ore from any one mine was fairly uniform. As the production increased, however, and the field of available ore was broadened to include deposits previously regarded as unprofitable, it became necessary, in order to simplify shipping, to grade ores according to their composition and, further, to mix ores differing in composition to produce certain grades. Finally, it became quite common for one mine to ship several different grades, and for the ore from several mines to be grouped under one name. These conditions brought about a necessity for knowing the exact composition of the various ores, and whether or not, in the case of mixed ore, each cargo was of the grade guaranteed. This grading is done by sampling the ore in the cars as fast as they are loaded at the mine or beneficiation plant in lots not exceeding five, and making a rapid but accurate analysis of the determining elements. From the results of this analysis, the class or grade of the ore is fixed, and its allotment into a certain group can be made. This is the work of the grader, who, from the analysis of the cars as submitted to him, makes a theoretical cargo in which the contents in silica, iron, phosphorus and possibly manganese, the determining factors in the value of an ore for its particular purpose, must fall within certain predetermined limits. It is very difficult to grade to more than two components, and usually the grading is done to iron and silica, or to iron and phosphorus, unless the deposits have been separated by nature into bodies of basic and bessemer grades, when the grading may include iron, phosphorus, and silica.

TRANSPORTING THE ORES

The lake ores now supply all the furnaces in Western New York, Western Pennsylvania, Ohio, Illinois, and Indiana, as well as those in the ore producing states of Michigan, Wisconsin, and Minnesota. In order to reach these markets, the ores must be transported for distances varying from 300 to more than 1000 miles, depending upon the locations of both the mine and the furnaces. The cost of transporting this ore by rail alone would be a serious handicap to some furnaces, but fortunately the chain of Great Lakes affords a cheap mode of transportation for the greater part of the long

as well as the short distances. Nearly all the ore mined in the ranges, then, goes first by rail to a harbor on Lake Michigan or Lake Superior, where it is loaded on ore-carrying boats that carry it either down Lake Michigan to Chicago or Gary or through Lake Huron and Lake Erie to ports farther south. For most of the ore, even these lower lake ports are not ultimate destinations, and another haul by rail is required to place it at the furnaces.

Now, to return to the grading of the ore and what was there referred to as a theoretical cargo or boat load which may weigh from 3000 to 21,000 tons, depending upon the size of the boat. When the cars containing this theoretical cargo reach the dock at the shipping port, they are unloaded into the dock pockets, one on top of the other, three to six cars to a pocket, in such order as to mix the ore as much as possible. The ore is then allowed to flow from these pockets into the hatches of the steamer (Figure 6—17), thus, again mixing the ore. Then the boat proceeds to her destination, where the ore is unloaded by electrically or otherwise operated grabs (Figure 6—18), which process of unloading still further tends to mix the ore and make it uniform. All this mixing of the ore is not to be thought of as merely incidental to the operations, but as a necessary course of procedure, for uniformity in the ore is a very important requirement in the successful operation of the blast furnaces. If the ore is unloaded at the works located on the lakes, it is sampled for analysis during the unloading by an elaborate system and is dumped upon its appropriate stock pile; if for inland works, such as Pittsburgh, it is placed in cars and shipped to the works, where it is thoroughly sampled. This sampling and analysis is common to all consumers, in fact, and is employed as a check on the sampling, analysis, grading, and mixing at the mines, and on all the operations of handling involved in delivering each grade of ore to the furnaces. The cars are then unloaded upon a stock pile from which the ore can be used as needed, or directly into the furnace bins, if the ore is needed for immediate use.

Mining and Grading in Winter—In winter the procedure as outlined above has to be changed somewhat. During a part of November, and all of the winter months of December, January, February, and March, the ore cannot be transported over the lakes because of the ice. On this account, operations in the open pit mines of the Mesabi District are suspended in winter; but in all the underground mines, both of the old ranges and the Mesabi, mining is continuous throughout the year, and the ore mined during the nonshipping season must be stock-piled. As this ore is removed, it is carefully sampled, and average samples are analyzed daily. The results of these analyses, supplemented by those made in the work of exploration that is constantly carried on in advance of the mining, make it possible to calculate the average composition of each stock pile at the beginning of the shipping season in the spring. This stock, therefore, may be combined, if necessary, with the ore direct from the mines to make up cargoes of definite and known composition.

Chapter 7

FLUXES AND SLAGS

SECTION 1

FLUXES

Function of Fluxes—Any metallurgical operation in which metal is separated by fusion from the impurities with which it may be chemically combined or physically mixed (as in ores) is called **smelting**. Since in iron smelting both these conditions with respect to impurities are always present, the production of crude iron involves two processes: (1) the reduction of the metal from its compounds and (2) its separation from the mechanical mixture. Many of the impurities associated with iron ores are of a highly refractory nature, that is, they are difficult to melt. If they should remain unfused, they would retard the smelting operation and interfere with the separation of metal and gangue. *To render such substances more easily fusible is the primary function of a flux.* Some elements, being reduced almost simultaneously with the iron, dissolve in it, or even combine chemically with it. Some other compounds, already combined with the metal in the raw materials, refuse to be separated from it unless there be present a substance for which they have a greater chemical affinity under the prevailing conditions. *To furnish a substance with which these elements or compounds may combine in preference to the metal is the secondary function of a flux.*

Chemistry of Fluxes—The selection of the proper flux for a given process is chiefly a chemical problem requiring a knowledge of the composition and properties of all the materials entering the process. With this knowledge at hand, the selection will be governed by the well-established physical and chemical laws which apply at smelting temperatures. These laws are not unlike those which govern chemical reactions at ordinary temperatures. Of most importance are the laws concerning the formation of salts from the interaction of acids and bases. Practically all of the slag-forming compounds that enter into a smelting or refining process may be classed as either "acids" or "bases" by virtue of the fact that they will react with each other to form compounds which are analogous to the salts formed in reactions taking place in water solutions. In like manner, stronger or more active "acids" and "bases" will replace weaker or less active ones in slag compounds. The substances which are conventionally considered to be "bases" at the high temperatures encountered in smelting and refining are those which are compounds of the elements forming basic compounds in ordinary chemical reactions in water solutions, such as calcium, magnesium, sodium, etc.; while the most important acid impurities are compounds of silicon and phosphorus. These latter elements normally form acids in water solutions. In addition to these are compounds which are analogous to the amphoteric compounds or elements which are capable of acting as acids or bases depending on the conditions imposed. Since one of the functions of

a flux is to neutralize or form slag with unwanted impurities, it will naturally follow that to remove "basic" impurities, an "acid" flux will be required and to remove "acid" components, a "base" will be used as the flux. It is fortunate that, generally speaking, the slag compounds formed by reactions between acid and basic materials have lower melting points than the reacting compounds, so that the primary function of a flux, rendering impurities more fusible, is simultaneously fulfilled, although there are occasions where a "neutral" material may be used to obtain slag fluidity. In most ores the impurities will be both acid and basic, with the acid materials usually predominating. In certain Southern ores, however, the acids and bases are so well balanced, or can be made so by mixing, that the ores are classed as **self-fluxing**. A brief discussion of the more important fluxes used in the iron and steel industry follows.

Acid Fluxes—Silica (SiO_2) is the only substance that may be classed as a strictly acid flux. For this purpose it is available as sand, gravel and quartz in large quantities and in a sufficiently pure state. In acid-steelmaking processes, silica seldom is added as a flux, for the lining of the furnace supplies what may be required. On occasion, silica may be used in basic processes where excess lime has been charged, or where the raw materials are too low in silicon. Acid-Bessemer slags may be charged in the blast furnace for their beneficial fluxing or scouring effect on accumulations on the furnace bosh, as well as, incidentally, to recover the iron and manganese they contain. Gravel is used frequently for the same purpose. Siliceous iron-bearing materials are charged in making blast-furnace grades of ferrosilicon, but the function of silica in this instance is to provide a source of silicon rather than to act as a flux.

Basic Fluxes—While in acid processes iron and manganese oxides act as bases, they are not normally added for this purpose and cannot strictly be classed as fluxes. The chief natural basic fluxes are limestone, composed principally of calcium carbonate, CaCO_3 , and dolomite, composed principally of calcium-magnesium carbonate, $(\text{Ca,Mg})\text{CO}_3$. Either dolomite or limestone may be used as a blast-furnace flux, but the former is not so satisfactory as limestone in cases where it is desired to minimize the volume of slag produced, or where large amounts of sulphur must be removed by the slag. Availability and cost are important factors when choosing between them. A high-magnesia slag is not desirable for cement manufacture, but for ballast or concrete aggregate produces a much harder product which is less subject to slaking. Representative compositions of limestone and dolomite are given in Table 7—I, together with typical compositions for calcined or "burnt" limestone and dolomite. Lime is usually added as calcined or

Table 7—I. Representative Compositions of Limestone, Burnt Lime, Dolomite and Burnt Dolomite (Natural State Determinations).

Ingredient	Limestone	Burnt Lime	Washed Dolomite	Burnt Dolomite

"burnt" lime in the basic open-hearth process where more than the amount furnished by the limestone charged is found to be needed at a later stage of the heat. *Dolomite is not used in the basic open-hearth process except as a refractory.*

The effectiveness of a natural basic flux is reduced by the chemically-acid impurities it contains, since these also must be neutralized by some of the chemically-basic compounds in the flux. The effectiveness of a basic flux is expressed in terms of "available base," by which is meant the amount of basic substance that remains in the raw flux after its own acid contaminants have been satisfied.

Alumina—Although alumina is seldom employed as a flux, it deserves mention at this point because it is present in a large number of raw materials and is therefore unavoidable. In slags it may function as an acid or as a base, depending on the conditions imposed. For instance, in highly siliceous slags it may form aluminum silicates, while in the presence of a large excess of a strong base such as lime, it may form calcium aluminates.

Neutral Fluxes—For the purpose of making slags more fusible without changing their acidity, basicity, or oxidizing properties, neutral substances having low fusion points may be added. For this purpose, fluorspar is the most commonly used substance. A typical composition of fluorspar, in which calcium fluoride is the active ingredient, is given in Table 7—II.

Table 7—II. Typical Composition of Fluorspar (Dry Basis)

Ingredient	Per Cent
CaF ₂	81.0
SiO ₂	4.75
Al ₂ O ₃ , Fe ₂ O ₃	1.00
S	1.00
CaCO ₃	Remainder

Sources of Fluxing Materials—As mentioned earlier, sources of silica for fluxing purposes are sand, gravel, quartz, and, in some cases, such material as used brick from silica-brick lined vessels or ladles. Acid-Bessemer and acid open-hearth slags or siliceous ores may be used in special instances. Limestone of fluxing quality is distributed widely and underlies most of the area drained by the Mississippi and Ohio Rivers. The larger portion of the limestone for the Pittsburgh steelmaking district originates in Western Pennsylvania, while that for the Lakes district is obtained from the northeastern section of the lower peninsula of Michigan, and from northern Ohio. Dolomite is quarried chiefly in eastern

West Virginia for use in the Eastern district. Fluorspar for use in the steel industry comes primarily from western Kentucky and southern Illinois.

Preparation of Fluxes for Use—The fluxes previously mentioned usually require only drying and sizing before use. Those materials which may be added to a slag, such as fluorspar and burnt lime, are desired small in size so that they may rapidly react to produce the desired results. Limestone and dolomite for blast-furnace use and limestone for use in the basic open hearth require careful sizing because the rate of calcination of these materials is controlled primarily by the surface exposed. The chemical reactions involved are:

A. For pure calcium carbonate:

B. For pure magnesium carbonate:

Both reactions are endothermic and are affected by pressure and temperature. Reaction A comes to equilibrium under a pressure of one atmosphere of CO₂ at a temperature of about 1625° F, and it is evident that calcination will begin at temperatures much below steel-making temperatures. For a given limestone at a given calcining temperature the surface area (screen size and shape) determines the time for complete calcination. The times for complete calcination at 1780° F of different sizes of an ordinary grade of limestone are about as follows:

Screen Size of Stone (In.)	Calcining Time (Hr.)
1	1 to 1½
2	2 to 3
3	3 to 4½
4	4 to 6
5	5 to 7½
6	6 to 9

Thus, in a blast furnace, for example, it is possible through a sizing of the stone to have its decomposition completed at the position in the stack desired for most economical operation. In general, the preferred size for blast-furnace stone is 2 to 4 inches, while for open-hearth use the preferred size is 4 to 8 inches, although in the latter case the stone size may be varied more widely in order to cause the occurrence of the lime boil at the desired time.

Burnt lime is produced by the calcination of limestone in large rotary kilns of the general type described later in Section 5, which may be several hundred feet long. They are inclined at a slight angle and are fired from the lower end. The slow rotation moves the stone from the upper charge end and during its passage through the kiln

it decomposes to calcium oxide or burnt lime and is discharged at the fired or lower end, the carbon dioxide

passing out with the waste gases from combustion of the fuel.

SECTION 2

SLAGS

Slag is the name applied to the fused product formed by the action of the flux upon the gangue of an ore or fuel, or upon the oxidized impurities in a metal. As previously indicated, they result from the neutralization of bases and acids, hence, correspond roughly to the salts formed in water solution during chemical reactions at ordinary temperatures. The word cinder is used interchangeably with slag, but cinder is also applied to refuse in a solid form. The subject of slags in general is a very large one and the discussions in this section are intended merely as introduction to the subject.

Metallurgical Functions of Slags—On account of their fusibility, chemical activity, dissolving power, and low density, slags furnish the means by which impurities are separated from the metal and removed from the furnace in both iron and steelmaking processes. Incidentally, as in the open hearth process, for example, the slag performs other important functions. Lying upon the molten metal, it serves as a blanket to protect the metal from the action of hot gases, and as slag is a poor conductor of heat, it may sometimes prevent overheating of the metal and, at other times, conserve its heat. Since slags possess the power of dissolving oxides, they are used effectively as a means of controlling the composition of the bath of metal beneath. In the metallurgy of iron-making, the importance of slag cannot be overemphasized. In the blast furnace, the combination of the composition of the slag and the temperature of the metal and slag in the hearth furnishes the means of control of the sulphur and silicon contents of the iron produced, as discussed in Chapter 12. In open hearth steelmaking, particularly in the basic process, the slag is the only means by which the impurities in pig iron (excepting carbon)

are removed. To the metallurgist, a knowledge of the properties of slags, their chemical behavior, formation temperatures, fusibility and fluidity, and how to control these factors, is essential.

No attempt has been made in this brief statement to do more than call attention to the metallurgical importance of slag in blast furnace and in open hearth furnace operations, both of which are later covered in detail. Slag is of equal metallurgical importance in other processes such as the electric furnace, the Bessemer and other special processes, including duplexing. In each case, the metallurgical features of the slag formed are described under the individual process in later chapters.

Secondary Metallurgical Uses of Slag—In addition to its metallurgical functions in different processes, slag, when recovered from one process, may possess properties which make it useful or of value in other metallurgical operations. Thus, basic open hearth slag, with its high iron and manganese contents, is an excellent addition to the blast furnace burden, as these elements are reduced, and valuable metallics recovered which otherwise would be wasted. Open hearth slag of special composition, such as the tapping slag described later, is of value in making up the blast furnace burden. The iron units in this slag are recovered in the pig iron, the lime present in the slag aids as a flux, and the manganese is reduced and increases the manganese content of the pig iron.

Special methods or treatments have been developed or are in the course of development for the recovery of valuable alloys from electric furnace slag. The value of these processes, as in those mentioned above, is largely one of economics; i.e., does the value of the material recovered amount to more than the cost of its recovery?

SECTION 3

SLAGS AS BY-PRODUCTS

After performing their useful functions in a particular process, the slags produced often are of value for other purposes.

Blast furnace slag, depending upon its chemical composition and the physical form in which it is permitted to solidify, has many uses. Three general physical types are produced by different methods of cooling from the molten state; i.e., air-cooled, granulated, and expanded. **Air-cooled slag**, the "crushed slag" of commerce, is prepared by pouring the molten slag onto a slag bank or into a pit. After solidifying and cooling, the slag is excavated, crushed and screened. **Granulated slag** is prepared by three general methods: pit, jet, or dry granulation. **Pit granulation** consists of running the molten slag directly into a pit of water, producing a relatively coarse, friable product. In the jet process, a modification of the pit process, the stream of molten slag is broken up by a high-pressure water jet as it falls into the pit, and the granulated slag falls into the water in the pit to be quenched further. A product called dry granulated slag is made by a mechanical device using relatively small amounts of water. **Expanded or lightweight slag** is the

foamed product produced when molten slag is expanded by applying a limited quantity of water or with a controlled quantity of water and air or steam. The amount of water used under controlled conditions is less than that required for granulation; consequently, a relatively dry, cellular lump product is formed in the process. **Lightweight slag** is made commercially in the United States in three general ways, which may be designated as the machine process, the jet process and the bank process. The objective of the machine process is the expansion of the molten slag in a revolving device with steam generated by contact of the slag with a controlled quantity of water. In the jet process, one or more high-pressure jets of water impinge on a stream of molten slag, and the product falls into a dry pit. The bank process is the application of water under pressure as the slag flows from the ladle down the face of the bank. The water is controlled or regulated by the pitman in order to expand the slag to a clinker properly and to prevent granulation. Expanded slag has a relatively high structural strength with good insulating and acoustical properties. Nearly 2,300,000 tons were produced in 1953. The

material is normally produced in two sizes, the coarse ranging from $\frac{1}{2}$ " to No. 4 sieve and the fine from No. 4 sieve to dust. The cellular structure of the aggregate consisting of many nonconnecting cells surrounded by thin walls of slag is more pronounced than with the air-cooled slag.

Specific Uses of Blast Furnace Slag—Blast furnace slag has been very successfully put to many commercial uses, some of which are summarized in Table 7—III. The steps in processing the slag to convert it to useful forms are shown schematically in Figure 7—1.

Slag output in 1953, as reported by the Bureau of Mines, totalled 30,511,603 short tons, a new record high well above the previous record of 26,899,376 short tons turned out in 1951. The value of the 1953 output was \$40,067,294. The recovery of iron by slag processors during 1953 totalled 353,833 short tons.

For concrete making purposes, slag has many desirable features. The strengths, both compressive and flexural, developed in slag concrete are at least equal to those resulting from the use of other types of aggregate. Typical slag concrete weighs approximately ten pounds per cubic foot less than concrete made of other materials, this statement of course not applying to concrete made from special lightweight aggregate, of which lightweight slag is one.

Slag is especially adapted to macadam road construction for the particles, due to their shape, interlock in such a way as to form a very good mechanical bond. The slag fines used to bind or fill the voids of larger

macadam sizes are also very desirable because of the cementing value.

The characteristic rough, pitted surface of slag particles, together with the fact that it is hydrophobic in nature, makes it exceptionally suitable for bituminous construction of all types. These characteristics provide an excellent bond between the bitumen and aggregate, and also permit the application of a sufficiently heavy film of bitumen on the aggregate surface to assure durability and long life in the pavement. Slag sand is particularly valuable for use as fine aggregate in bituminous concrete of both the hot and cold-mix types.

Slag has proved to be an excellent aggregate for airport runway construction of the macadam, bituminous or concrete types.

As railroad ballast, slag has been used successfully by the leading railroads in the United States for many years. Many of the most heavily-traveled tracks in the country are ballasted with slag. More than 5,000,000 tons were so used in 1953. Another use for crushed as well as granulated blast-furnace slag is for agricultural purposes, in which it serves three functions: (1) to reduce soil acidity; (2) to alter and improve physical characteristics of soils; and (3) to supply essential plant nutrients which many soils lack. In regard to (3), however, blast-furnace slag is considered as a soil conditioner rather than as a fertilizer. It contains many of the mineral elements necessary for plant growth, notably manganese, boron, sulphur and iron. Its action as a soil conditioner is similar to that of basic open-hearth slags used widely in the South for this purpose, as discussed later.

Slag also has proved of value as trickle-filter media for sewage disposal. This is especially true in the northern states where the filter media is subjected to severe freezing and thawing as well as wetting and drying. Slag has withstood the extreme exposure in sewage-disposal filter beds to a remarkable degree with practically no breakdown, even after as much as thirty years of service.

Slag has been in great demand for many years for use as a covering for built-up bituminous roofs and as granules for covering asphalt shingles.

A demand for slag for use in the production of mineral wool in the past few years has materially increased. A large percentage of all mineral wool produced in the United States is made of slag. Slag is re-melted in a small cupola and the molten product, after reaching a desired temperature, is blown into wool by a jet of high-pressure steam or compressed air. The production of mineral wool from the molten slag as it comes from the blast furnace has, after much experimentation, not been found practical.

One of the earliest uses for blast-furnace slag was in the manufacture of cement. Slag with a low magnesia content is required for cement-making. In granulated form, such slag has been used in large quantities in the manufacture of portland as well as other types of cement. For portland cement it is used as a part of the raw material that is burned in the usual way to form clinker, which, in turn, is ground into cement by methods described in Section 5 of this chapter. Over 1,400,000 tons of blast-furnace slag were used for the making of cement in 1953.

Basic open-hearth slag has a more limited field of application as a by-product than has blast-furnace slag but, like the latter, it also has found an important use as a soil conditioner, especially in the southern states. In the northern states, with present steel-making practices, the phosphorus content of basic open-hearth slag is low compared to that of the basic open-hearth slags produced in the southern states where ores of a much higher phosphorus content are used.

FIG. 7-1. Schematic representation of the steps involved in processing blast-furnace slag to convert it to useful forms. The purpose of the multiple screens preceding the screened-slag bins is to sort the crushed slag into appropriate sizes.

The greatest production of basic open-hearth slag for use as a soil conditioner is produced at a plant in which the steel is produced by the duplex process involving use of acid converters and tilting basic open-hearth furnaces maintaining a dominant pool. In this process approximately 80 per cent of the next succeeding charge in the form of blown metal is washed through the refin-

ing slag of the previous heat impregnating the slag with phosphorus. The slag is then poured from the furnace over the fore plate into slag pots beneath the furnace, as described in Chapter 17 entitled "The Duplex and Triplex Processes."

Flush slags from the conventional open-hearth process also may be used as a soil conditioner.

SECTION 4

FUNCTIONS OF SLAGS AS SOIL CONDITIONERS

The chief food elements that plant life or vegetation obtains from the soil are potassium, phosphorus, and nitrogen, but, as mentioned previously, others such as iron, sulphur, and manganese are essential. For plants to thrive, soil conditions must be favorable, particularly with respect to humus content and basicity. Thus, if the soil is in clods, or if it is too acid or basic, unsatisfactory crop results are obtained, irrespective of the amount of fertilizer applied. An important function of slags is to correct such adverse conditions.

The chemical bases in slags consist mainly of lime, with some magnesia and small amounts of other basic compounds. The lime in slag, however, is in loose chemical combination with silica, iron, and manganese, so that it does not "burn" like ordinary agricultural lime nor revert to carbonate, but remains in a stable, almost neutral form, available as needed over long periods of time until exhausted.

While slags used for agricultural purposes cannot be called fertilizer, they do contain some fertilizing elements and, if of a suitable grade and properly prepared and applied to the soil, do promote conditions essential to profitable farming. Hence, they rightly are called soil conditioners.

The first basic slag used as soil conditioner was from the Thomas-Gilchrist or basic Bessemer process of steel-making. The possibilities of this slag as a soil conditioner and stimulant to plant growth were investigated first in England in 1884. Its use was adopted in Scotland in 1890, and the practice spread rapidly throughout Europe in succeeding years.

As early as 1900, a German investigator reported on the use of blast-furnace slag as a fertilizer, with special reference to the beneficial effects of soluble silica in the material. Comparatively little comprehensive research work on the agricultural value of blast-furnace slag has been done in the United States, although coordinated test work has been undertaken in recent years and is still in progress.

In the South, the Tennessee Coal and Iron Division of the United States Steel Corporation has been preparing and marketing basic open-hearth slag from their duplex-

ing process, as a soil conditioner since 1915. The high-phosphorus content of the slag, previously referred to, justifies economically the cost of preparation and freight charges of the product for use in that area. Originally, it was the aim of the company to produce a slag for agricultural purposes in which the citric-acid-soluble phosphoric-acid content was high enough to meet fertilizer specifications. However, experiments established the fact that slags with a much lower phosphoric-acid content were so useful as soil conditioners that it appeared best to aim for greater tonnages containing between 8 and 12 per cent phosphoric acid, rather than a limited tonnage of product with an extremely high content of phosphoric acid. Steps in its preparation are as follows:

The high-phosphorus slag from the tilting open hearth, after cooling, is delivered to the soil-conditioner plant and mixed with flush slag containing less phosphorus. The large slag cakes are first broken by the use of a heavy steel ball, after which large pieces of steel are removed by the use of a conventional electromagnet. The slag is then transferred by a grab bucket to a roller crushing unit which breaks it down to 1½-inch maximum size. Elevating conveyors then deliver the slag over a magnetic roller and vibrating screens from which the larger pieces of slag are returned to be recrushed and shot-steel scrap is loaded for use in the blast furnaces. That portion of the slag which passes through the screen is then conveyed to a conventional tube mill for final grinding.

From the tube mill the slag is conveyed to storage bins and thence to a bagging unit where once again it is passed through screens to remove all tramp particles. Samples for chemical analysis and fineness testing are taken hourly from the product discharged from the tube mill. The product is packaged in paper bags, each containing 100 pounds net weight and marketed under the trade name of "Ground Open Hearth Basic Slag." Phosphoric acid content ranges from 8 to 12 per cent; fineness 70 per cent through a 100-mesh screen. Facilities are available for the loading of this slag in bulk not only in railroad cars but spreader trucks as well.

SECTION 5

MANUFACTURE OF PORTLAND CEMENT

Portland cement is a finely pulverized material consisting of certain definite compounds of lime (CaO), silica (SiO_2), alumina (Al_2O_3) and iron oxide (Fe_2O_3). Its most familiar use is in concrete. Concrete is a mixture in which a paste of portland cement and water binds fine and coarse materials (sand, pebbles, crushed stone, crushed blast furnace slag, etc.) known as aggregates into a rock-like mass as the paste hardens due to the formation of new compounds through chemical action

between the original compounds of the cement and the water. In simple terms, concrete is a mass of aggregates held together by a hardened paste of portland cement and water.

Raw Materials—Based on the 1949 "Minerals Yearbook" published by the Bureau of Mines, approximately 68,621,000 tons of raw materials (exclusive of fuels and explosives) entered into the manufacture of 209,727,417 barrels of portland cement in the United States in that

FIG. 1-2. Schematic representation of cement-plant layout and equipment for producing Portland cement by the "dry" and the "wet" methods. (Courtesy Portland Cement Association.)

year. This is an average of about 654 lb. of raw materials for each barrel of finished portland cement weighing 376 lb. Loss of weight is caused by the process of calcination in which moisture, carbon dioxide and other gases are driven off in the kilns. Materials are chiefly high-calcium limestone, clay or shale, argillaceous limestone, blast-furnace slag and marl. Totals were:

Raw Material	Short Tons
Cement rock (argillaceous limestone)	12,628,494
Limestone and oyster shells	44,968,739
Marl	722,606
Clay and shale	6,698,408
Blast-furnace slag	847,375
Gypsum	1,543,198
Sand and sandstone	724,624
Iron-bearing materials	346,542
Other materials such as:	
diatomite, fluorspar, pumicite, flue dust,	
pitch, red mud and rock, hydrated lime,	
tufa, cinders, calcium chloride, sludge,	
grinding aids, and air-entraining com-	
pounds	140,999
Total	68,620,985

Also according to the Bureau of Mines, the following quantities of fuel were used by the portland cement industry in the United States and its territories in 1949 (for all cement-mill fuel consumption including the process of burning in the kilns, independent power production and other uses):

Coal (tons)	7,987,560
Oil (gallons)	192,637,116
Gas (cubic feet)	84,689,284,000

Based on figures from this same source relating to cement production and fuel consumption in those plants that use only one fuel exclusively, the following amounts of fuel were required to produce one barrel of cement:

Coal	115.1 lb.
Oil	8.44 gal.
Natural gas	1,519 cu. ft.

Dry and Wet Processes—There are two processes which may be used to make portland cement (Figure 7-2). These are called the "dry" and the "wet" methods. In the dry process, after the crushed raw materials are taken from storage, dried and blended in the proper proportions, the mixture is fed into huge rotating ball mills or impact mills of various types for preliminary grinding. The ball mills get their name from the hundreds of large steel balls inside them which are carried on ribs up one side of the rotating mill and cascaded down onto the material being ground.

The mixture then goes to a tube mill, which is similar to the ball mill except that the material is more finely ground by 40 to 50 tons of smaller steel balls. Some plants use combination ball-and-tube mills, called compartment mills. Motors up to 1,000 horsepower are required to operate them. Grinding is frequently done in circuit with air separators which remove the fine material from the mill discharge and return the coarse material for further grinding, effecting economies in grinding.

After the dry raw material is ground, it is carried to storage. Samples are analyzed for chemical content to insure uniform quality. Accurately proportioned amounts of the dry raw material are then ready to go to the kilns for burning.

The wet process is very much like the dry except that, at the ball mill, water is added and the material is ground wet to give it a thick, creamy, soup-like texture. The

cement makers call this slurry. Sometimes, this wet grinding is done in closed circuit with classifiers to remove finished fine material as fast as produced and return the coarse material for additional grinding. In this case, the finished slurry has a very high water content which is reduced in large thickeners before using the slurry as kiln feed.

The slurry is then pumped into tanks where it is tested and blended to the desired chemical composition. From the blending tanks, the slurry is pumped to large storage tanks to be held until needed for burning.

The Burning (Calcining) Operation—The prepared and blended mixture of raw materials is fed into rotary kilns, where the mixture is calcined or burned to what is known as cement clinker. Briefly described, a rotary kiln is a nearly horizontal steel cylinder, lined with suitable refractory brick and 6 to 12 feet in diameter and from 60 to 500 feet in length. Such kilns are continuous in operation. The raw material is fed continuously into the higher end of the long, inclined cylinder which rotates continuously at a rate of about one revolution per minute. By reason of the inclined position of the kiln and its rotary motion, the charge moves gradually and continuously toward the lower end of the kiln where it is discharged.

Heat for calcining the charge is supplied by combustion equipment that fires axially into the kiln at the discharge end. The direction of flame travel, therefore, is opposite to the direction of progress of the charge, and the charge is heated hotter and hotter as it travels toward the firing end. Pulverized coal, natural gas, or fuel oil is used as fuel. A temperature of 2800° F is attained in the hottest zone at the discharge end of the kiln. The heat serves two purposes: (1) to cause the desired chemical changes to take place in the raw mixture, and (2) to form clinker by fusing the transformed materials into small masses about the size of marbles.

The clinker resulting from the burning of the raw material in this way is then cooled and pulverized in equipment similar to that used for dry raw material grinding, together with a small amount of gypsum added to regulate the setting time, and becomes the portland cement of commerce.

A barrel of cement weighs 376 pounds net and equals four sacks of 94 pounds each. Each sack contains approximately one cubic foot. Cement has been shipped in cloth sacks or paper bags, in bulk on large jobs, and for export in wooden barrels or paper-lined cloth sacks. Today, nearly all cement is shipped in bulk or in paper sacks.

Chapter 8

REFRATORIES

SECTION 1

CLASSIFICATION OF REFRATORIES

Refractories are the chief materials used in the steel industry in the construction of all furnaces and in the lining of retaining vessels, as well as in the flues or stacks through which hot gases are conducted. At the risk of over-simplification, they may, therefore, be said to be materials of construction exposed to temperatures above a dull red. This material is expensive, and any abrupt failure in the refractories results in a great loss of time, equipment and product. Therefore, the problems of obtaining refractories suitable for each branch of the industry and a refractory best suited to each specific purpose are of supreme importance. Economics figure largely in the solution of these problems, as a refractory best suited for an application is not necessarily the longest lived, but the one which provides the best balance between initial installed cost and service performance. These balances are never fixed, but are constantly shifting as a result of the introduction of new processes or new types of refractories. History reveals that refractory developments have occurred largely as the result of the pressure for improvement caused by the persistent search for superior metallurgical processes. The rapidity with which these ever-recurring refractory problems have been solved has been a large factor in the rate of advancement of the iron and steel industry. To discuss the many factors involved in these problems and to provide information helpful to their solution are the objects of this chapter.

Refractories may be classified in a number of ways, no one of which is completely satisfactory. From the chemical standpoint, refractory substances, in common with matter in general, are of three classes; namely, acid, basic, and amphoteric or neutral. Theoretically, acid refractories should not be used in contact with basic slags, gases or fumes, while basic refractories should be exposed to no other conditions. Actually, for various reasons, these rules are continually violated. Also, with the possible exception of carbon, the existence of a strictly neutral refractory may be doubted. Hence, the time-honored chemical classification is primarily academic, and of little value as a guide to actual service possibilities. Classifications by use, such as blast-furnace refractories or open-hearth refractories are generally too broad and are constantly subject to revision. Mineralogically, refractories may be classified two ways; namely, with reference to the raw materials, and with reference to the minerals predominating after processing for use. For the present purpose, the following raw-materials classification is believed to offer the best possibilities for a clear understanding of the origin and nature of steel-plant refractories.

A. SILICEOUS GROUP

Quartzite—Quartzite or ganister is the most commonly used, and the purest, of the siliceous raw materials. Massive rock forms analyzing over 98 per cent SiO_2 , are

the chief raw materials for silica-brick manufacture, and are mined in Pennsylvania (Medina quartzite), Wisconsin (Baraboo quartzite), Alabama, Utah and California. Pure quartz pebbles are sometimes found loosely bonded by a matrix of fine silica and mica as a natural rock known as a conglomerate. The Sharon conglomerate in Ohio is of this type and is being increasingly used for silica-brick manufacture, as the impurities may be readily removed by washing. In recent years, it has been clearly demonstrated that the total Al_2O_3 and alkali content of silica brick must be kept under one per cent for satisfactory performance in open-hearth roofs, and preference is being given to even purer brick containing less than 0.5 per cent total impurities. For this reason, much care is taken to select and wash all silica raw materials used in producing open-hearth roof brick.

Sandstone—Sandstone, or firestone, is a sedimentary rock consisting essentially of bonded sand grains, and usually analyzing 90 to 93 per cent SiO_2 , 3 to 5 per cent Al_2O_3 , and some iron oxide and lime. It is relatively soft and often striated, thus permitting easy cutting or splitting into blocks or shapes for use in the raw state for lining soaking pits or acid Bessemer converters.

Mica Schist—Mica schist is a highly laminated micaceous silica rock of composition similar to sandstone, but generally slightly lower in silica. Like sandstone it is readily cut and is also used in the raw state for hot metal ladle and mixer linings in addition to linings for soaking pits and converters.

Siliceous Fireclays—While the term siliceous fireclays might properly refer to clays having a rather wide range in silica content, reference here is to those clays with a minimum of 75 per cent SiO_2 , which are employed in the manufacture of semi-silica brick, and are characterized by a very low percentage of impurities such as alkalies, alkaline earths and iron oxides. Somewhat less siliceous and often more impure clays are also widely used for mortars and daubing purposes with siliceous linings.

B. FIRECLAY GROUP

Chemically, clays are all hydrous silicates of alumina and occur widely distributed. They are identified as being plastic when in a wet and finely divided state (as by pulverizing, wetting, and mixing), rigid when dried, and vitreous when heated to a sufficiently high temperature. Clays may be residual or sedimentary, and have been formed by the natural decomposition or weathering of feldspathic rock. Ordinary varieties contain high percentages of combined water and impurities that render them unfit for use as high-temperature refractories. Impurities include alkalies, titania, compounds of iron, calcium and magnesium, and organic matter from various sources. Even in small quantities the alkalies, and the compounds of iron, calcium and magnesium are important fluxes and have a pronounced effect on the

refractory properties of the clay. The species used as a refractory is known as fireclay. Fireclays are of sedimentary origin, are usually associated with coal measures, and contain limited percentages of fluxing impurities. There are several varieties, namely:

Plastic Fireclay—A fireclay of sufficient natural plasticity to bond nonplastic materials.

Flint Fireclay—A hard or flint-like fireclay occurring as an unstratified massive rock, practically devoid of natural plasticity and showing a conchoidal fracture.

Nodular Fireclay—Also called burley or burley flint clay, nodular fireclay occurs in the form of a rock containing aluminous or ferruginous nodules, or both, bonded by fireclay.

Kaolins—While not fireclays, certain kaolins are highly refractory and are sometimes employed in the manufacture of fire brick. Kaolins are both sedimentary and residual, and quite pure, generally closely approaching the theoretical clay composition represented by the formula $\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot 2\text{H}_2\text{O}$.

C. HIGH-ALUMINA GROUP

This group includes those materials capable of serving for the production of refractories of higher alumina content than the maximum that can be provided by fireclays, namely, more than 47.5 per cent Al_2O_3 . Occurring naturally are two classes of minerals, those which are combinations of Al_2O_3 and H_2O , typified by bauxite and diaspore, and those which are combinations of Al_2O_3 and SiO_2 , typified by sillimanite, andalusite and kyanite.

Bauxite and Diaspore—Bauxite is a high alumina rock composed of $\text{Al}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$ and $\text{Al}_2\text{O}_3 \cdot \text{H}_2\text{O}$, found in Arkansas and South America. It is less used for refractories than diaspore, $\text{Al}_2\text{O}_3 \cdot \text{H}_2\text{O}$, although its use is now increasing as supplies of diaspore diminish. Diaspore is found chiefly in Missouri where it occurs in lenses or pockets chiefly as diaspore clay, a rock consisting essentially of diaspore bonded by fireclay. The best grades, upon calcination yield a product containing between 70 and 80 per cent Al_2O_3 . Impurities include iron oxides and titania.

Sillimanite, Andalusite, and Kyanite (Cyanite)—These minerals all have the formula $\text{Al}_2\text{O}_3 \cdot \text{SiO}_2$ and contain theoretically 62.9 per cent Al_2O_3 and 37.1 per cent SiO_2 . On heating, all form mullite ($3 \text{Al}_2\text{O}_3 \cdot 2 \text{SiO}_2$) and a siliceous glass, but differ in the ease with which this decomposition takes place, kyanite being easiest to convert (about 2415° F) and sillimanite the hardest (about 2785° F). Indian kyanite is most desirable for high-alumina refractories, although South African and domestic kyanites are now being used, sometimes blended with the Indian kyanite. Brick made from these materials, usually referred to as sillimanite or mullite brick, are generally superior in high-temperature volume stability and spalling resistance to other types of high-alumina brick.

Fused alumina, an electric-furnace product, is frequently used as an addition in high-alumina refractories.

D. MAGNESIUM-SILICATE GROUP

This group includes the olivines and serpentines. Olivines have the general formula $2 \text{RO} \cdot \text{SiO}_2$, in which the RO may be MgO, CaO, FeO, or MnO. The most common refractory olivine is a mixture of forsterite ($2 \text{MgO} \cdot \text{SiO}_2$) and fayalite ($2 \text{FeO} \cdot \text{SiO}_2$), and is found primarily in North Carolina. Serpentines are hydrous magnesium silicates of the general formula $3 \text{MgO} \cdot 2 \text{SiO}_2 \cdot 2 \text{H}_2\text{O}$. Forsterite is the most desirable magnesium silicate for refractories, and is generally the end product aimed for in employing these minerals.

E. MAGNESIA-LIME GROUP

In this group have been classed all natural and synthetic magnesites, brucite, and dolomite. These constitute the most important group of refractories for basic steelmaking processes, as all are sources of magnesia, MgO, the best basic refractory known.

Natural magnesite, MgCO_3 , is rarely found in a pure state, but contains varying percentages of silica, alumina, iron oxides and lime, so that on calcination the MgO content generally ranges from 80 to 85 per cent. Silica is the most objectionable impurity and varies from 4 to 10 per cent. Formerly, much magnesite was imported from Austria, but for several years, the steel industry has relied almost exclusively on sources in the state of Washington and in Canada.

Magnesia is derived synthetically from sea water brines, well brines, dolomite and brucite, or processes combining brines and dolomite. The production of magnesia or, more popularly, sea-water magnesite by these means has increased rapidly in recent years, and this material is now used extensively in the manufacture of basic brick and granular refractories.

Brucite is a hydrate of magnesia found chiefly in Nevada and is used largely in conjunction with dolomite in the manufacture of granular refractories.

Dolomite is a double carbonate ($\text{CaCO}_3 \cdot \text{MgCO}_3$), which calcines, evolving 47.8 per cent as CO_2 , leaving 30.4 per cent CaO and 21.7 per cent MgO. Principal impurities are silica and alumina, but large deposits are found in several localities such as Illinois and Ohio, which closely approach the theoretical composition. Thus, for best refractory service, a dolomite should contain more than 21 per cent MgO, less than 1 per cent SiO_2 , and less than 0.5 per cent Al_2O_3 , in a crude state. From the standpoint of consumption, dolomite exceeds all other refractories, as in either the raw, calcined, or dead-burned state*, it is the chief mainstay in open-hearth-bottom maintenance.

F. CHROMITE GROUP

Chrome ores in general consist of a highly refractory spinel ($\text{RO} \cdot \text{R}_2\text{O}_3$) composed of FeO, MgO, Al_2O_3 and Cr_2O_3 , in various proportions, and less refractory associated silicates. Chrome ores of widely different compositions are suitable for refractory purposes, the chief limitations being lime, iron oxide, and silica. Most of the suitable refractory grades are obtained from the Philippines, Cuba, India, Russia, South Africa, Greece, and Turkey.

Chrome ore is used either alone or in various combinations with magnesia in brick manufacture, and as a granular or plastic refractory for a number of purposes.

G. CARBON GROUP

This group includes natural and artificial graphites, and various types of coal, coke, and tar.

Graphite deposits occur widely distributed, both in this country and abroad. It is often mixed with calcareous or siliceous rock and requires expensive purification. Flake graphite, as found in Ceylon, is preferred for crucible and stopper-head manufacture, in which the graphite is bonded with high percentages of clay. The amorphous graphites found in Mexico are sometimes used to enhance the slag-resistant properties of plastic-clay refractories.

Baking of molded coke and tar or coke and pitch mixtures will produce artificial graphite or carbon shapes, although much higher temperatures are required for

* See Section 2B, Granular Refractories—Fired Products for explanation of terms "calcined" and "dead burned."

graphitization. Carbon is used extensively as a refractory, and may be made from foundry coke, petroleum coke, or anthracite coal, bonded with pitch or tar of low moisture content. Such refractories are being used increasingly for blast furnace refractories and other applications where reducing atmospheres prevail.

PREPARATION OF REFRACTORIES

Steel-plant refractories are used in a wide variety of forms, the preparation of which may vary from little

more than the operation of mining, to highly complex grinding, screening, molding, and firing procedures demanding precise control throughout. Hence their preparation will be discussed according to their use in the massive, granular, or finely-divided form, and according to whether these forms are in the raw, fired, or chemically-bonded state.

The chemical compositions of the various types of refractories discussed above are given in Table 8—I on Page 182.

SECTION 2

A. MASSIVE REFRACTORIES

Raw State—Sandstone and mica schist are invariably used in the form of large blocks sawed or split from the raw rock, and further shaped as needed on the job. To minimize spalling from heat, these blocks are laid flat, with laminated edges exposed to the heat. Chrome ore and olivine have been similarly used for open-hearth bridge walls, but their use in block form has practically ceased. A siliceous insulating brick, accurately cut to standard brick size from natural diatomaceous earth, is sometimes used to back up fireclay-brick walls. Such brick have superior insulating value as compared with brick made from the same material by conventional methods, although that property will be greater with heat flow normal to the laminations.

Burned Products—Fired brick and shapes of all types of refractories constitute the bulk of refractories used in the massive form. The processes by which these brick and shapes are produced are basically similar although, as might be expected, the nature of the raw materials and the wide variety of properties desired in the final products have caused the adoption of a number of variations in these processes.

The first step is the mining of raw materials. Mining methods depend upon the location, size, and uniformity of the deposit. For the most part, deposits are underground, and mining methods are similar to those employed in the various types of underground mining and quarrying. However, large uniform deposits, such as are characteristic of some plastic clays and dolomites, are worked more economically by the open-pit method, even though this may involve stripping of many feet of overburden. More exacting refractory requirements and diminution of established sources of some materials are constantly forcing changes in methods of mining. For example, the quarrying of flow ganister on mountain sides for use in silica-brick manufacture is gradually giving way to the mining of ledge rock in some localities in Pennsylvania.

Following the mining, some purifying operations may be necessary. At present, these may be merely visual selection, weathering to remove soluble salts, or only a simple washing operation as employed with some flint clays and increasingly so with some quartzites. However, the recent employment of a flotation process for removal of lime and dolomite impurities from natural domestic magnesites is indicative of the trend toward raw-material beneficiation.

The future will likely see the adoption of more ore-dressing practices by the refractory industry, although careful study will be required to determine which procedures are applicable and can be justified with each material.

The next step is one of crushing, grinding, screening, and mixing. These are important operations, as, in large measure, they control the density, porosity, strength,

spalling resistance, and thermal characteristics of the brick, although there are no general rules for their control. The fineness of the grinding must be varied for different raw materials and different mixes, and with a given material the grinding to obtain a certain effect depends upon equipment available for subsequent operations. Formerly, no screening was done, but by 1930 it was being used as a means of controlling the particle size which, in turn, is one of the means of controlling the significant properties of porosity and bulk density of brick, and led to the important developments of super-duty fireclay brick and vastly-improved basic brick. Mixing may consist of adding fines to coarse material of the same kind to control the grain or particle size, or of adding one material to another; for example, lime to quartzite and plastic clay to flint clay to act as binders; burned clay or refractory to a plastic mix to control shrinkage; or magnesite to olivine, magnesite to chrome ore, bauxite to clay to change the composition and character of the brick.

Forming operations may be carried out by hand molding, extrusion, extrusion and pressing, dry pressing, drop molding, and pneumatic ramming. In 1905, all brick were formed by hand. The moist mix (15 to 20 per cent moisture) was tamped into forms set on pallets, the forms were removed, the pallet set upon a "hot floor" to "temper" and the tempered brick were repressed in a hand-operated press, thoroughly dried and then fired in a rectangular or round down-draft periodic kiln. By 1913, however, a goodly percentage of the brick was being formed by machine.

In the stiff-mud process, the wet clay mix, after tempering with 12 to 15 per cent moisture in a pug mill, is extruded through a die by a power-driven auger or plunger, and the column is cut with taut wires into the sizes desired. This may be the final processing before drying and firing, or the shapes may be given a final shaping and branding in a repress machine. This process is used almost exclusively for fireclay products.

A more universal forming method is power pressing or dry pressing. In this process, the refractory is thoroughly mixed with from 3 to 8 per cent moisture, and this relatively dry mixture is fed to steam-, electric-, or hydraulic-powered presses, where measured quantities are pressed in shape under pressures varying from 1,000 to 10,000 pounds per square inch. Dry-press products are generally more true to shape and more uniform in size than stiff-mud products. The density of the dry-press products may be greater or less, depending on the degree of particle-sizing control exercised and the pressure employed, but the cold strength is generally less than that of stiff-mud brick. Obviously, dry pressing lends itself to a wider range of refractories than extrusion processes, and fireclay, silica, and all types of basic brick are frequently made in this manner.

A measure employed to improve the bulk density of brick with either of the foregoing processes is **deairing**. In the stiff-mud process, the auger chamber is evacuated. While the effectiveness varies with different clays, remarkable improvements in the properties of the clay column and the final product are often effected by this means. During pressing in the dry-press process, the mold box is evacuated of air through small holes in the pressing pads.

Drop molding is a process exclusive to the manufacture of silica brick, as the prepared mix has little or no plasticity. In this operation, the wet mixture of crushed ganister and about 2 per cent lime is elevated by bucket conveyor and dropped from a height of 15 to 20 feet into multiple molds below resting on pallets. The mold is struck off and removed, and the brick placed on dryer cars while still on pallets. Organic binders are often used to enhance the weak green strength of silica brick and thus minimize breakage.

Many large or special shapes of superior refractories which cannot be pressed in the usual way are produced by **pneumatic ramming** in steel molds or by special **vibrating devices**. The mix employed is very low in moisture and very carefully sized, as the aim is generally to obtain high density. The mix is fed in slowly and uniformly during ramming.

Refractories are burned or fired in either periodic kilns of the round down-draft or rectangular type, or in tunnel kilns. In **periodic firing**, the dried green brick are set in the kiln, the kiln is gradually brought to the required temperature, held for varying periods, cooled and drawn. This cycle will vary from about two to four weeks, with a production of about 25,000 to over 50,000 nine-inch equivalent, (cubical content of a standard $9 \times 4\frac{1}{2} \times 2\frac{1}{2}$ -inch brick), per cycle. In **tunnel-kiln firing**, the green brick loaded on small cars are passed slowly through a long tunnel-shaped brick structure in a direction counter to the flow of gases, whereby they pass progressively through the pre-heating, firing, and cooling zones, generally taking 3 to 5 days for the trip. Temperature of firing is important, because both the quality and properties of the brick may be affected. By maintaining an oxidizing or a reducing atmosphere, the subsequent behavior of most brick car. be changed, and by controlling the rate of heating and the firing temperature, changes in the crystalline structure can be effected, which, in turn, may affect the service performance of the brick. In general, the objects in firing are: (a) to drive off hygroscopic and combined water; (b) to bring about desired chemical changes—drive off CO_2 and oxidize iron and sulphur compounds, organic matter, etc.; (c) to effect transformations of the mineral constituents and convert them to most desirable stable forms; and (d) to effect necessary combinations and vitrification of bonding agents.

By other developments in technique of manufacture, the porosity of fireclay and silica brick can be greatly increased, making the brick good insulators and considerably lighter in weight. Hence, they are designated as **lightweight** or **insulating brick**. Processes for making these brick aim for high porosity, preferably with fine pore structure. This is accomplished by mixing a bulky combustible substance, like sawdust or ground cork, or a volatile solid, such as naphthalene, with the wet batch, by forcing air into the wet plastic mass, or by mixing into the batch reagents which will react chemically to form a gas and a product not injurious to the brick.

Carbon refractories, as sometimes used in blast-furnace linings, are truly massive refractories, commonly being used in blocks 22 inches by 30 inches in cross section, up to 15 feet in length, and exceeding 6000

pounds in weight. As previously mentioned, these blocks are made of calcined anthracite coal and/or low-ash coke with a tar bond, and are formed by extrusion, after which they are baked in coke at a temperature of approximately 1800° F for long periods, seven weeks sometimes being required to complete a cycle. Smaller shapes and brick of standard size are likewise made and are replacing the larger blocks in many blast-furnace wall installations.

Chemically Bonded Products (Basic Brick)—Since their introduction about 1923, the manufacture of chemically-bonded basic brick has steadily increased, until today unburned basic brick constitute approximately one-half of the total basic-brick production. In this process, a suitable chemical-bonding material is mixed with the raw materials and the brick are formed under pressures sometimes exceeding 10,000 pounds per square inch. Careful sizing of the raw materials and thorough mixing to insure uniform distribution of the bond are necessary. If the brick are to be metal encased, this process permits the pressing of the steel jacket onto the brick during the actual forming operation. After forming, all that is necessary is a thorough drying out at less than 500° F to develop maximum cold strength, which often exceeds that of burned basic brick.

Refractory Concrete Products—Refractory concrete is made of sized refractory aggregates, such as calcined flint clay, crushed fireclay brick bats, chrome ore, olivine, or magnesite, and a hydraulic bond, usually calcium aluminate cement. Aggregate-cement ratios may vary from 4 to 1 to 10 to 1. Calcium aluminate cements are employed because of their rapid setting and, more important, their ability to retain their water of hydration, and hence their bonding power, to considerably higher temperatures than Portland cement. Besides the use of such concretes for pouring refractory structures in place, they are often used to cast special shapes, such as burner blocks, on the job.

Electrocast Products—The electrocast process consists of mixing raw materials of high purity in proper proportions, heating them to complete fusion in an electric furnace, and casting in forms, very much as liquid iron or steel is cast. By 1935, many refractory bodies, consisting essentially of fused mullite, had been produced. Since that time, other products, consisting of various combinations of chrome, magnesite, alumina, and zirconia have also been produced. Advantages of the process are almost complete lack of voids, a narrow range of melting, and better control of chemical properties.

B. GRANULAR REFRACTORIES

Raw State—The chief refractories used in the raw state in granular form are clays, chrome ore, and dolomite. Clays coarse enough for this classification are seldom used without further reduction on the job, blast-furnace-taphole clays being the principal application. Granular chrome ores are used in open-hearth front-wall maintenance as ground, or for reheating-furnace hearths and open-hearth doors when plasticized with clay and bonded with sodium silicate. Crushed raw dolomite is used extensively for open-hearth maintenance, principally for building up banks, where its consumption may vary from 10 to as much as 100 pounds per ton of steel produced.

Fired Products—Fired granular products include dolomite, magnesite, and other special basic refractories. Two types of dolomite are recognized in this category. Calcined dolomite, often called single burned, is produced in this country by heating the natural rock to a temperature somewhat above the decomposition temperature of the dolomite or generally to about 2000° F. This

product consists of crushed porous granules which are very active chemically and tend to slake rapidly upon exposure to the atmosphere. Its use is decreasing. Dead-burned, or clinkered dolomite is a product made by calcining or dead-burning dolomite at temperatures of approximately 3000° F, usually in rotary kilns, using iron oxide as a dead-burning agent. The iron oxide forms calcium ferrites in the dead-burning operation. This has an important function in mineralizing and shrinking the refractory in the burning operation and in helping to coalesce the refractory into a monolithic mass in the open-hearth furnace. This is the most satisfactory form in which to use dolomite, but as it is also the most expensive, it is often used in combination with raw or single-burned dolomite.

Magnesite for making furnace bottoms, for furnace maintenance, and for brick making is always used in the dead-burned state, produced, like dolomite, by firing at high temperatures in rotary kilns. While it is the important refractory in making new open-hearth bottoms, its consumption per ton of steel, in contrast to dolomite, varies from about one to two pounds.

Special granular refractories are used principally for the basic ramming and patching materials which have been introduced since 1939. These are carefully-sized, chemically-bonded preparations composed of dead-burned magnesites or magnesia-dolomite mixtures. The latter generally contain a minimum of 60 per cent MgO, the balance being so proportioned between lime and silica as to form a predominance of dicalcium silicate when clinkered in a rotary kiln. To prevent the dusting of dicalcium silicate on cooling, it is necessary to prevent its sudden inversion from the beta to the gamma form. This is accomplished by stabilizing with small amounts of mineralizers such as Cr_2O_3 , B_2O_3 and phosphates, or combinations of these. These special ramming mixtures are now widely used for open-hearth-bottom making, as they are quicker to install, provide more accurate contours, and generally are more uniform in composition, than burned-in magnesite bottoms.

Another group of special granular refractories is the fireclay-base plastic refractories. These consist generally

of sized mixtures of raw and calcined clays, often containing sodium silicate or organic bonds, which are shipped wet or dry for applications where a rammed refractory may substitute for brickwork. Such plastic refractories may also be made with super-duty clays, kyanite, or other high-alumina materials as additions.

The refractory concrete products referred to above are often made from dry, prepared mixtures called **castables**. As these are sold ready for mixing with water, they must be included as granular refractories.

C. FINELY DIVIDED OR PULVERIZED PRODUCTS

Raw State—Clays for brick laying and various bonding purposes are about the only refractory used in steel mills in the raw, finely-divided state. However, large tonnages of such clays covering a considerable range in refractoriness are employed.

Processed Products—These include the various heat-setting and air-setting cements and mortars. They are produced for laying every type of brick, and, hence, may have as many different base materials, the principal ones for steel-plant use being silica, fireclay, chrome, and magnesite. Silica cement, or silica fireclay, is usually made of finely-ground quartzite or sand to which is added about 10 per cent plastic clay and possibly an organic binder, although in a few superior grades, the undesirable introduction of alumina from the clay is avoided by using dolomite or lime bonds with other additions to provide the necessary workability for brick laying. Fireclay cements differ from plastic fireclay refractories chiefly in respect to fineness, as they also consist of mixtures of raw and calcined clays. The heat-setting varieties rely on vitrification for bonding, while the air-setting types usually contain liquid or dry sodium silicate and, hence, may be shipped wet or dry. Chrome and magnesite cements may contain small clay additions for workability, and like fireclay cements, may also contain sodium silicate or organic binders. All prepared cements generally are ground to completely pass a 30-mesh screen with substantial percentages passing a 100-mesh screen.

SECTION 3

PHYSICAL AND CHEMICAL CHARACTERISTICS OF REFRATORIES AND THEIR APPLICATION TO MEET SERVICE CONDITIONS

The foregoing discussions have indicated that a wide variety of refractories, possessing nearly every extreme in characteristics normally used to differentiate between materials, have found a place among the requirements of steel-plant processes. Obviously, these requirements must be equally diversified. Analysis of service conditions in general shows that refractories are required to withstand:

- (1) All ranges of temperature up to 3200° F.
- (2) Sudden changes in temperature—"thermal shock."
- (3) Stresses—mainly compressive, at both high and low temperatures.
- (4) The action of slags, ranging from acid to basic in character.
- (5) The action of molten metals, always at high temperatures and capable of exerting great pressures and buoyant forces.
- (6) The action of gases, including SO_2 , CO, Cl, CH_4 , H_2O , and volatile oxides and salts of metals, even volatile metals. All are capable of penetrating and reacting with the brick. SO_2 may react with oxides

in the brick to form easily-fused salts. CO, penetrating fireclay brick, breaks down to C and CO_2 in the presence of iron carbides, the carbon being deposited in the brick and causing its disintegration. Zinc in the vapor phase has a similar effect. At relatively low temperatures, steam and water vapor exert a slaking effect on dolomite and magnesite refractories. And nearly all refractories are apt to be subjected to, and adversely affected by, volatile iron and alkalis.

- (7) The action of dust in gases, which may be fluxing or non-fluxing, and acid or basic.
- (8) Impact and abrasive forces at both high and low temperatures, as those in the stack of a blast furnace.

At the same time a refractory is being subjected to one or more of the above conditions, it may be required to function as a storehouse for heat, as in checkers; as a conductor of heat, as in the walls of coking chambers; or as an insulator.

With such an array of service requirements it would

FIG. 8-1. Pyrometric cone equivalent (P.C.E.) of various refractories.

be extremely helpful to have ways of predetermining the suitability of a refractory for a given application. However, it is difficult, or in many cases, impossible, to duplicate these widely variable service conditions in the laboratory. Even were this not the case, time and cost are effective barriers to the development of practical tests which will provide information necessary for positive selection of the proper refractory. Therefore, the standard tests which have been devised, generally within these limitations, primarily provide gages of performance which, while invaluable for quality control, must be judiciously correlated with additional fundamental knowledge of refractory behavior and with service observations before they can be effectively used by consumers. In many instances, information is not available to satisfactorily bridge the gap in this manner, and special tests must be devised.

Thus, by comparison with other materials of construction, refractories appear to suffer in the degree of precision with which they can be applied to fill a certain need. To appreciate this situation it is necessary to know something of the high-temperature behavior of refractories and to recognize that this behavior is the end result of a complex and inextricable combination of physical and chemical factors. Some of these factors are fixed, as they constitute the inherent properties of the materials employed, or of the products of their reaction with other materials in service. Others, mostly physical, may be varied within limits to produce certain desired behavior. In their combined effect on the cold and hot

strength, resistance to spalling, resistance to deformation under hot load, permeability and other measured properties, these factors often oppose each other; hence a particular refractory may represent one or more compromises, with a sacrifice of excellence in one characteristic in order to achieve it in another more important for a given application. In the following discussion of refractory characteristics, these matters are emphasized rather than the details of the tests used in refractory evaluation.

Fusion or Softening Temperature—The fusion of most refractory materials is not clear cut, but a more or less gradual transition from solid to liquid. The amount of liquid that can be tolerated by a refractory and still leave it in a serviceable condition is largely governed by the viscosity of the liquid and the type of crystallization of the solid phases present. For example, fireclay refractories may develop liquid and actually start to soften as low as 1800° F, but due to the high viscosity of the liquid their limiting service temperature may be several hundred degrees higher. An arbitrary procedure has, therefore, been established for gaging the refractoriness of such materials, and is called the **Pyrometric Cone Equivalent**, or P.C.E. test, in which the softening behavior of small cones of the refractory are compared with that of standard pyrometric cones of known time-temperature softening behavior. The P.C.E. is reported as the number of that standard cone whose tip touches the supporting plaque simultaneously with a cone of the refractory being investigated when tested in accordance

with the Standard Method of Test for Pyrometric Cone Equivalent (A.S.T.M. Designation: C-24). The composition of the standard cones and the temperature range covered make the P.C.E. test most applicable to alumina-silica refractories. Figure 8—1 gives the P.C.E. of various refractories and the corresponding softening temperatures when heated under the test conditions. It must be recognized that the end points of pyrometric cones primarily reflect the influence of time and temperature, and hence are reproducible only under identical conditions. A cone used in a kiln fired for a week will soften completely at a temperature which would leave it unaffected in the short P.C.E. test. Fireclay refractories behave similarly, the influence of time being strikingly shown in the case of ladle brick. Normally, maximum service temperatures of fireclay brick are considerably below P.C.E. temperatures, but low-P.C.E. ladle brick are successfully used at temperatures 300° F above their P.C.E. temperatures because the duration of this exposure is seldom more than an hour at a time.

It is not particularly disturbing that the P.C.E. test is not equally satisfactory for silica and basic brick, as other tests provide a far more realistic appraisal of refractoriness. The melting point of pure silica (3140° F) is certainly not impressive when compared to that of other materials, and yet silica brick, containing 95 to 98 per cent SiO_2 , so far have successfully resisted replacement by more refractory materials in open-hearth roofs attaining temperatures frequently exceeding 3000° F. This is because silica brick approach the sharp melting behavior of a pure compound, and, aided by a strong crystalline structure, remain rigid to within a few degrees of the temperature of complete fusion.

On the other hand, the main constituents of basic brick (magnesite, chrome, chrome-magnesite and forsterite) all melt at temperatures far above any encountered in steel plant service. Periclase (MgO) melts at 5070° F, chrome spinel, $(\text{MgO}, \text{FeO}) \cdot (\text{Cr}_2\text{O}_3, \text{Al}_2\text{O}_3, \text{Fe}_2\text{O}_3)$, above 3600° F, and forsterite ($2 \text{MgO} \cdot \text{SiO}_2$) at 3470° F. However, the raw materials for basic brick contain other minerals considerably lower in refractoriness which can form fluid liquids at temperatures as low as 2400° F, and as these materials are the matrix of most basic brick, they largely govern the melting behavior of the brick as a whole, particularly as the basic minerals lack the strong, interlocking crystalline structure of the silica and alumina-silica minerals. Fortunately,

these low-refractory minerals are subject to control, so that their detrimental effects can be minimized or even eliminated by corrective additions, special firing treatments, and proper distribution.

Porosity and Permeability—Unless expensive measures are resorted to, all manufactured refractories will contain a certain amount of voids, the amount, size, and continuity of which have important influences on refractory behavior. The apparent porosity indicates the percent of the total volume which is open pore space, and hence is a measure of the area of surface available for reaction with slags and gases. The total porosity is the percentage of the total volume which is voids, whether open or closed, and thus, depending on the nature of the material, method of manufacture and degree of burn, may only slightly exceed the apparent porosity or be more than twice as great. The effect of porosity on various refractory properties will be discussed later, but in general, increasing the porosity adversely affects the cold strength, resistance to deformation under hot load, heat capacity, thermal conductivity and resistance to attack by gases and slags. Within limits, increasing porosity will improve spalling resistance, but as this can also be achieved in brick of low porosity, it is evident that as a general rule, far more can be gained in performance from refractories possessing the lowest possible porosity. The porosities typical of various types of refractories are given in Table 8—II.

Porosity bears but little relation to permeability, which is a measure of the rate of diffusion of liquids and gases through the refractory, and thus is governed by the size and number of connected pores or channels which are continuous from one side of the refractory to the other. Permeability to liquids will increase with increasing temperature as the viscosities of the liquids will decrease, while just the opposite is true of gases, whose viscosities increase at higher temperatures. While permeability is not commonly determined, and no standard tests exist in this country, it is undoubtedly important in such applications as blast-furnace linings where disintegration frequently occurs as a result of penetration by carbon monoxide and subsequent carbon deposition within the brick.

Bulk Density and True Specific Gravity—Like porosity, the bulk density of refractories is used as an indication of the voids/solids ratio, but is meaningless in this sense without reference to the true specific gravity of

FIG. 8—2. Typical curves of linear expansion of various types of refractories.

Table 8—II. Some Typical Physical and Thermal Properties of Refractories

Refractory	Apparent Porosity %	True Specific Gravity	Bulk Density		Cold Strength		Behavior Under 25 Psi Load			Spalling Resistance
			Lbs. per Cu. Ft.	Oz. per Cu. In.	Crushing on End Psi	Modulus of Rupture Psi	Percent Deformation	When Held 1½ Hrs. At	Temp. of Failure (° F)	
Silica Brick:										
Conventional	21-30	2.30-2.38	102-115	0.94-1.06	1000-3700	400-1500	2950-3020	Below 1100° F— Poor
Super Duty ..	22-26	2.33-2.35	105-115	0.97-1.06	1000-3000	350-800	3060-3090	Above 1100° F— Good
Fireclay Brick:										
Super Duty—Normal Burn ..	13-20	2.65-2.75	136-151	1.26-1.40	900-4000	600-1300	2.5-9.0	2640° F	Good to very good
Super Duty—Hard Burn	8-15	2.69-2.76	141-151	1.31-1.40	2500-4500	900-1300	0.7-4.0	2640° F	Poor to very good
High Duty—Normal Burn ...	12-25	2.60-2.70	128-142	1.18-1.32	1000-6000	400-2000	1.0-10.0	2460° F	Fair to good
High Duty—Hard Burn	10-17	2.70-2.78	134-146	1.24-1.35	3000-8000	1300-2500	2.0-5.0	2640° F	Poor to good
High Duty—Siliceous:										
New Jersey	26-30	2.60-2.70	116-121	1.08-1.12	1800-2300	450-600	0.5-1.5	2460° F	Very good
Texas	21-25	2.60-2.70	125-132	1.16-1.22	1500-2500	600-1100	0.5-1.5	2460° F	Good
Intermediate Duty	18-21	2.55-2.65	128-140	1.19-1.30	1500-4000	900-1600	2.0-6.0	2460° F	Fair
Low Duty	18-21	2.55-2.65	126-145	1.17-1.34	2500-4500	900-1500	2.0-10.0	2460° F	Fair
Ladle Brick	10-18	2.64-2.67	130-146	1.20-1.35	3000-12000	Fair
High Alumina Brick:										
50% Al ₂ O ₃	20-24	2.75-2.85	125-135	1.16-1.25	2500-4000	1000-1500	4.0-6.0	2640° F	Good

Magnesite-Chrome:										
Chemically Bonded	3.60-3.80	185-205	1.71-1.90	2000-5000	750-1000	2700-2850	Good
Carbon Block	19-25	1.96-1.97	94-100	0.87-0.92	3500-10000	0	3100° F	Very good

the refractory. Thus, the bulk density of a chrome brick having a true specific gravity of 4, but a porosity of 25 per cent is still much greater than that of a dense fireclay brick whose porosity is 10 per cent, but whose true specific gravity is only 2.6. Bulk density may be expressed in a number of ways, those most common being grams per cubic centimeter (bulk specific gravity), pounds per cubic foot, or ounces per cubic inch. Being thus the mass of refractory material in a given volume, an increase in the bulk density of a given refractory increases the strength, volume stability, heat capacity, resistance to slag penetration, and generally, resistance to structural spalling, or spalling resulting from vitrification caused by fluxing with dusts and slags.

The true specific gravity of a fired refractory may differ substantially from that of the raw materials from which it is made, owing to conversion of the mineral constituents. For example, quartzite with a specific gravity of 2.65 converts on heating to cristobalite and tridymite with specific gravities, respectively, of 2.32 and 2.26, so that the resultant specific gravity of fired silica brick reflects the degree of conversion, and is a most reliable test for adequacy of firing treatment. The conversion of kyanite to mullite is another example. Table 8-II shows typical bulk densities and specific gravities of various refractories.

Thermal Expansion and Volume Changes—From the early steps in manufacture throughout their service life, refractories are subject to various types of volume changes. As these changes may affect product uniformity and service performance they are of concern to both manufacturer and user. Most familiar of these volume changes is the reversible thermal expansion, or dilation that practically all materials exhibit on heating and lose on cooling. Figure 8-2 shows typical curves of linear expansion for various types of refractories. Those which have a uniform expansion rate generally present the least difficulties when furnace temperatures fluctuate widely, and of these, those with the lowest total expansion, as a general rule, are less subject to thermal spalling. Such is the case with fireclay refractories. Silica brick, as previously mentioned, possess varying proportions of the silica minerals cristobalite, tridymite and unconverted quartz, depending on the heat treatment. As each of these silica forms has its own characteristic expansion with sudden changes accompanying inversions from low- to high-temperature forms, the curve for a silica brick will reflect its mineral composition to some extent. However, most of the expansion from all sources takes place below 1060° F, hence, if care is taken in heating and cooling below dull-red heat, silica brick behave admirably. In fact, one of the major problems in the application of basic brick to open-hearth roofs arises from the continuing high-temperature expansion of basic brick, which, while uniform, causes a "working" of such roofs with temperature changes in ranges that have no effect on silica roofs.

Permanent volume changes may be either expansion or contraction. The latter is first encountered in drying molded refractories, particularly clay brick, and must be accurately controlled to make a uniform product. Further shrinkage may take place on firing. Finally, if the refractory is used at temperatures above that at which it was fired, shrinkage may occur, or it may be caused by fluxing with dusts or slags and subsequent vitrification. Permanent expansion may also take place on firing refractories. Thus silica brick, because of the previously indicated decrease in specific gravities of the higher-temperature forms of silica, will expand about 13 per cent on firing. Some fireclay brick may also exhibit what has been termed **secondary expansion** on

firing or reheating. This has been attributed to an ex-foliation of the clay grains, and is to be distinguished from the bloating or vesicular structure development brought about by gas evolution and expansion in an overheated and hence pyro-plastic clay body. While generally indicative of misapplication of refractories, the latter condition is actually desired in ladle brick as it is conducive to the formation of a monolithic, steel-tight ladle lining. In service, refractories may also permanently expand. The action of alkalis on fireclay refractories to form alkali-alumina silicates with an accompanying expansion of about 12 per cent causes surface peeling of such refractories, as sometimes observed in open-hearth and blast-furnace-stove checkers. The expansion or "bursting" of basic brick on absorption of iron oxide at high temperatures is another example.

Cold Strength—The mechanical strength of refractories, as determined by modulus of rupture or cold crushing tests, is generally far more than that required to meet any dead loading encountered in construction. Nevertheless, we are interested in strength. Refractories must be handled a great deal before they are finally put in service, and it is naturally desired that they survive this handling with a minimum of breakage, abrasion and lost corners. Soft-burned clay brick, particularly if dry pressed, may be very friable and easily broken but still possess a crushing strength above 1000 pounds per square inch. As cold strength reflects the heat treatment a refractory receives in manufacture, and as this heat treatment affects porosity, bulk density, refractoriness under load, and abrasion resistance, considerable general information on any specific burned refractory can be obtained from strength tests with sufficient correlation. For this reason, cold-strength requirements are often used in the specification of refractories. The ranges in crushing strength and modulus of rupture for various refractories are shown in Table 8-II.

Strength and Behavior Under Load at High Temperatures—The cold strength of refractories is governed mainly by the amount of glassy bond present, the hot strength by the changes brought about in that glassy bond by heat. Generally, with increasing temperature, the glass gradually becomes a viscous liquid, although the initial softening temperature and the temperature range of viscous flow may vary widely between different types of refractories. Thus, to different degrees, all refractories at some temperature exhibit plastic flow, and if subjected to pressure, the subsequent behavior will depend on the amount of pressure and the duration and rate of its application, on the amount and viscosity of the liquid present, and on the crystalline structure of the solids. Loaded heavily and rapidly as in normal compression testing, all refractories will fail in shear until temperatures are reached at which they contain so much liquid of such low viscosity that almost instant deformation occurs. Under such conditions, the compressive strength or modulus of rupture may not change materially below temperatures of initial liquid formation, but will then rapidly decrease.

Of far more significance, however, is the behavior under light, sustained loads comparable to those encountered in service, and numerous tests have been devised to measure the amount or rate of deformation occurring under specified conditions of time, temperature and stress. While prolonged tests are especially informative to the refractory user, all standard tests are of relatively short duration, although increasing attention is being given to the longer tests, particularly those aimed at the determination of the almost imperceptible flow or "creep" of refractories at temperatures immediately

below and above those of the initial liquid formation.

Fireclay refractories have the longest softening range and are most susceptible to plastic deformation. Under standard test conditions, consisting of heating a 9-inch brick on end under a 25-pound per square inch load in $4\frac{1}{2}$ hours to test temperature (2460°F for high-duty brick; 2640°F for super-duty) and holding for $1\frac{1}{2}$ hours, the temperature of initial deformation and the total amount of deformation will depend on the flux content, the degree of burn, and the porosity. Impurities such as lime, magnesia, iron oxides and alkalis, will lower the temperature of initial liquid formation and the viscosity of that liquid, and hence increase deformation. Hard-burned brick will show much better resistance to load than a soft-burned brick made of the same clays, due in part to greater mullite development, but primarily due to the fact that harder firing has developed a more refractory glassy phase which forms a liquid of initially higher viscosity at test temperatures. Increasing porosity decreases the ability of a particular brick to resist deformation under load, as the voids provide opportunity for a brick to compress on itself and also decrease the amount of refractory available in a given volume to resist pressure. The temperature of initial deformation under load will vary widely for a given brick with deviations from standard test conditions. For example, a fireclay brick deforming initially at 2250°F in the standard test might not deform until 2350°F with a lighter load or a faster heating rate, and conversely, might deform as low as 2000°F with a much heavier load or with that temperature maintained for several hours.

The behavior of high-alumina brick under load is similar to that of fireclay brick, although the temperature range of plastic deformation will be higher the greater the alumina content.

Due to their strong, interlocking crystallization and purity, silica brick show little evidence of plastic deformation under load, remaining rigid under a load of 25 or even 50 pounds per square inch until they fail by shear at temperatures varying from 3000°F to 3100°F . The latter temperature, however, is attainable only by the super-duty types containing a maximum of 0.5 per cent of the impurities Al_2O_3 , TiO_2 , and alkalis. Because of their strong crystalline structure, silica brick may be more than 30 per cent molten at the temperature of failure.

Basic brick, like silica brick, generally fail under hot load by shearing, but lacking the intercrystallization characteristic of silica minerals, practically all resistance to failure resides in the liquid phases present. In chrome and magnesite brick, these liquids may be low in refractoriness and viscosity and failure will occur in the range of 2400°F to 2500°F . However, with the development of a refractory forsteritic matrix, as in burned forsterite and chrome-magnesite refractories, failure may not occur until 2950°F to 3050°F under a load of 25 pounds per square inch in a rising temperature test. Unburned basic brick usually fail 100°F to 200°F below the temperatures of failure of burned brick of the same composition.

A notable exception to the general rule that magnesite brick are weak in load-carrying ability, is the recently-developed high-purity sea-water-magnesite brick containing in excess of 96 per cent MgO . Such brick, even if unburned, normally will not shear under load, and have been found to deform less than 3 per cent at temperatures in excess of 3300°F .

Carbon refractories show little or no loss in strength and no deformation under load throughout the range of steel-plant temperatures.

Typical load test data for various refractories are shown in Table 8—II.

Heat Capacity and Thermal Conductivity—The heat capacity of a refractory at a given temperature is a function of its bulk density and its specific heat at that temperature. The thermal conductivity is a measure of the rate of heat transmission through the refractory. Both properties are increased with increasing bulk density and hence decreased with increasing porosity. As refractories may be used to confine, store, or transmit heat, the thermal conductivity desired will vary widely with the application. While a wide range in conductivity is available in commercial refractories, if the insulating types are included, it is not always possible to use that refractory whose conductivity is best suited to the job. Thus in the majority of cases, it is desired to confine heat, but it was previously noted that in a majority of cases high bulk density was also desirable from a service standpoint. With refractories used for heat storage and transmission, such as checker brick, no conflict in properties exists, as high density is desired both for stability and increased heat storage and conductivity.

Typical conductivity curves for general types of refractories are shown in Figure 8—3. It will be noted that

FIG. 8—3. Typical thermal conductivity curves for general types of refractories.

at the temperatures common to steel-plant operations, the differences in conductivity found in these refractories at low temperatures are greatly reduced. The accuracy of these higher-temperature determinations is often questionable, although standardization of test methods in recent years has greatly improved the reproducibility of results from different laboratories. However, actual heat flow through furnace walls in service still may differ considerably from calculations. Thus the conductivity will change with the alterations in structure and composition of the hot face; the rate at

which heat is carried away from the cold face affects the flow through the wall; and the gas pressure within the furnace has a great effect, not only on the heat flow but on refractory life as well, as positive pressures will drive heat in, increasing the depth of vitrification and fluxing.

Resistance to Thermal Shock (Spalling)—One of the major causes of refractory destruction is spalling, which is the breaking away of pieces of refractory from the hot face, thus exposing fresh surfaces. Spalling may result from too-rapid expansion or contraction of the hot face of the refractory with sudden temperature changes, called **thermal spalling**. Spalling also may result from changes in the hot face brought about by flux absorption or vitrification which set up zones in the brick which differ in expansion and sensitivity to thermal shock from the original brick, or shrinkage may occur, so that pieces separate; this is termed **structural spalling**. A third type, **mechanical spalling**, may result from mechanical abuse, as in removing slag accumulations from refractory surfaces, or may be caused by shifting loads and stresses, particularly in arches, so that refractories are pinched and crack off.

The properties of refractories which most influence their resistance to spalling are thermal expansion, elasticity (ability to yield to stress without rupture), and strength. Because of their low thermal expansion, fireclay refractories as a class have the best spalling resistance, but since the elasticity and strength are strongly affected by the degree of burn, particle size and porosity, wide variations exist. Thus a soft-burned,

coarse-grained, porous brick has higher elasticity and higher thermal-spalling resistance at low temperatures than a hard-burned dense brick, but may be expected to fail from structural spalling more readily at high temperature, due to greater shrinkage and flux absorption.

Basic refractories have high expansion coefficients and vary from very poor to fair in spalling resistance, magnesite and chrome being the poorest, and chromemagnesite being the best, particularly if chemically bonded.

As indicated earlier, the spalling resistance of silica brick varies from very poor to excellent, depending on whether they are subjected to temperature fluctuations below or above 1100 °F, respectively.

Abrasion Resistance—The resistance of refractories to abrasion and erosion is primarily a function of the strength. As strength is governed by degree of burn, some correlation also exists between abrasion loss and porosity and bulk density. While no standard hot-abrasion test has been adopted, there are some indications that the strength-abrasion loss relationship holds at higher temperatures, in which case resistance to abrasion might not be expected to change appreciably below 2000 °F, but to decrease at higher temperatures. Variations of the standard rattler test for paving brick are sometimes used in refractory testing, and more recently, an accelerated test employing a sand blast has been devised. For fireclay refractories, this test indicated a rapid decrease in abrasion loss with small increases in modulus of rupture to 1700 pounds per square inch, with further increases in strength being far less effective.

SECTION 4

REACTIONS AT ELEVATED TEMPERATURES

Discussions of the high-temperature behavior of refractories thus far have tended to emphasize the influence of various physical factors, and have given but little indication that behavior also reflects the working of immutable laws governing the high-temperature reactions occurring not only within the refractories themselves but between refractories and oxides encountered

in service. Until comparatively recent years, little was known of these reactions, and improvements in refractory products were slow, as they derived primarily from trial and error, and were generally physical in nature. Today there are available an ever-increasing number of phase-equilibrium diagrams which have proved invaluable guides to the production of superior refractories

FIG. 8-4. Phase diagram of the Al_2O_3 - SiO_2 system.

and to the correction of service difficulties. An indication of the importance of such data is found in the studies on the steel-plant refractory-oxide systems being carried out at the Pennsylvania State University under the sponsorship of the American Iron and Steel Institute. However, it should be recognized that these diagrams are not without limitations in their use to predict or explain refractory behavior. For example, the various systems have been explored with pure oxides and represent equilibrium conditions, while refractories are rarely pure and seldom in equilibrium, either as manufactured or in service. Because of this complex nature of refractories, information is often needed on reactions involving so many oxides that the usefulness of systems involving no more than three oxides is minimized. Finally, and most important, the diagrams give no information on such significant matters as viscosity of the liquids formed or the rate at which reactions proceed. Since it will be shown that under certain conditions many of the commonly-used refractories apparently can be liquefied to the point of destruction at temperatures encountered in steel-plant service, we are often vitally concerned in the rate at which reactions progress toward equilibrium and failure. As excellent compilations of diagrams have been published (see references at end of chapter), only a few are reproduced here.

Figure 8-4 shows the $\text{Al}_2\text{O}_3\text{-SiO}_2$ system which applies to silica, fireclay, and high alumina refractories. It will be noted that the lowest temperature at which any liquid is developed in the system is 2914°F , while for those compositions more aluminous than mullite ($3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$) or above 71.8 per cent Al_2O_3 , no liquid is developed below 3326°F . A eutectic occurs at the composition 94.5 per cent SiO_2 and 5.5 per cent Al_2O_3 . It is evident that if bonding and other manufacturing difficulties could be overcome, quite good refractories could be made of the pure oxides, even in the high-silica range. In fact, the semi-silica type brick containing about 80 per cent SiO_2 represent a practical approach to this condition. Such brick, because of their low impurity content, are superior in load-carrying ability to many far more aluminous brick having a higher PCE. The pronounced effect of the impurities present in most commercial refractories in this system can be appreciated by comparing the temperatures at which they deform initially under load with the initial liquid temperatures of 2914°F or 3326°F indicated in the diagram. The oxide impurities largely responsible for lowering the refractoriness of fireclay refractories are CaO , MgO , FeO , Na_2O , and K_2O , and these are also encountered in service.

Figure 8-5 shows the $\text{FeO-Al}_2\text{O}_3\text{-SiO}_2$ system. Here

FIG. 8-5. The $\text{FeO-Al}_2\text{O}_3\text{-SiO}_2$ system.

FIG. 8-6. The $\text{CaO}-\text{Al}_2\text{O}_3-\text{SiO}_2$ system.

we see that with unlimited amounts of iron oxide available for reaction with any but the purest end members of the $\text{Al}_2\text{O}_3-\text{SiO}_2$ series of refractories, the formation of some liquid can be expected even below 2000°F , and that very damaging amounts will be formed at the higher temperatures common to steel processes. This is particularly true as iron-oxide-bearing liquids are characteristically very fluid.

Figure 8-6 is the diagram of the $\text{CaO}-\text{Al}_2\text{O}_3-\text{SiO}_2$ system, which is most applicable to reactions of fireclay refractories with blast-furnace slags, but capable of supplying some information on other reactions involving refractories, as those occurring with the more complex open-hearth slags, or in the bond formed in magnesite brick. This system has also been useful in predicting behavior of silica brick, which will be discussed later.

The reactions of alkalis with alumina-silica refractories have recently been clarified by the publication of both the $\text{Na}_2\text{O}-\text{Al}_2\text{O}_3-\text{SiO}_2$ and the $\text{K}_2\text{O}-\text{Al}_2\text{O}_3-\text{SiO}_2$ systems by the Geophysical Laboratory. These systems are reproduced in Figures 8-7 and 8-8. It is evident that the refractoriness of alumina-silica refractories will be

seriously affected by very small amounts of Na_2O , less than 1 per cent being sufficient to lower the temperature of initial liquid formation to less than 2000°F , while approximately 10 per cent is sufficient to completely liquefy the more siliceous alumina-silica compositions at 2200°F . K_2O has a similar effect in amounts up to 10 per cent, but whereas Na_2O continues to lower the melting point with greater additions, the reverse is true of K_2O additions in the range of 10 to 20 per cent.

Small percentages of impurities are far more critical in silica brick than fireclay brick, and alkalis are the worst offender, although fortunately they seldom occur in amounts greater than 0.3 per cent. The percentages of Na_2O , K_2O and Al_2O_3 required to lower the melting point of pure silica from 3140°F to 3050°F are, respectively, 1.4, 1.9 and 3.1 per cent.

Another very serious fluxing agent for fireclay refractories is MnO , as can be seen in the diagram of the $\text{MnO}-\text{Al}_2\text{O}_3-\text{SiO}_2$ system in Figure 8-9. It will be noted that this system is quite similar to the $\text{FeO}-\text{Al}_2\text{O}_3-\text{SiO}_2$ system.

Because the raw materials for silica brick lack both a

FIG. 8-7. The $\text{Na}_2\text{O}-\text{Al}_2\text{O}_3-\text{SiO}_2$ system.

natural bond and a high melting point, care must be taken that the required bonding addition has the minimum effect on refractoriness. Figure 8-10 shows the $\text{CaO}-\text{SiO}_2$ system and explains why lime is universally used for this purpose. With additions of CaO to SiO_2 , the melting temperature remains unchanged between 1 and 27.5 per cent CaO , due to the formation of two immiscible liquids. We have already seen that no such phenomenon occurs in the $\text{Al}_2\text{O}_3-\text{SiO}_2$ system, and by referring again to the $\text{CaO}-\text{Al}_2\text{O}_3-\text{SiO}_2$ system, we find that only a small amount of Al_2O_3 is required to destroy the $\text{CaO}-\text{SiO}_2$ immiscibility. In fact, the effect of minor increments of Al_2O_3 on the liquid development of silica brick is such that the temperature of failure under a load of 25 pounds per square inch will decrease approximately 10°F for each 0.1 per cent increase in Al_2O_3 in the 0.3 to 1.2 per cent range of Al_2O_3 between super duty and conventional silica brick. Figure 8-11 of the $\text{FeO}-\text{SiO}_2$ system shows that FeO , like CaO , also forms two immiscible liquids when added to SiO_2 , thus greatly increasing the tolerance of silica brick for FeO . Furthermore, as with CaO , a small amount of Al_2O_3 can eliminate this immiscibility.

As atmospheric conditions in steel-plant furnaces may range from highly reducing to highly oxidizing, the form of iron oxides present may vary from FeO to Fe_3O_4 . Accordingly, Figure 8-12, showing the system $\text{FeO}-\text{Fe}_3\text{O}_4-\text{SiO}_2$, as recently determined by Muan in the AISI-sponsored studies at Pennsylvania State University, is of considerable importance. Thus, it is seen that the lowest-melting liquids occur from reaction of FeO and SiO_2 , and that at temperatures in the range of 2650° to 3030°F less liquid, and a less siliceous liquid, will be produced with either Fe_3O_4 or Fe_2O_3 than with FeO ,

due to the greater extent of the two-liquid region under oxidizing conditions. Hence, under oxidizing conditions, an open-hearth silica roof will have more tolerance for iron oxide, and therefore will be more durable.

The simple binary system $\text{CaO}-\text{MgO}$ shown in Figure 8-13 contains a eutectic approximating the composition of dead-burned dolomite, but it is evident that the whole series, within itself, is very refractory. However, as no binary compound is formed, dead-burned dolomite exists as a mixture of the two oxides, each free to act more or less independently. From a refractory standpoint, MgO behaves admirably, but the far more chemically active CaO is a decided trouble-maker in two respects. First, CaO is very reactive with iron oxides, forming low-melting calcium ferrites, and hence is readily fluxed by high-iron-oxide slags. Second, it imposes a major limitation on dolomitic refractories by its tendency to hydrate, regardless of the degree of previous heat treatment. Hence, if dolomite is to be used for other than a granular hearth-maintenance material, the lime must first be stabilized by combination with other oxides, usually silica, which forms dicalcium silicate.

It is evident that the refractory value of dolomite resides largely in the oxide MgO , and this is likewise true of the magnesium silicate olivine, and of course, the various types of magnesites. The chief characteristic of MgO accounting for its popularity as a refractory for basic steel processes is its great tolerance for iron oxide. Figure 8-14 shows that MgO and FeO form a continuous series of solid solutions which are amply refractory even when their composition is more than half FeO . This situation prevails under reducing conditions. Under oxidizing conditions MgO reacts to form magnesioferrite ($\text{MgO} \cdot \text{Fe}_2\text{O}_3$) which contains 80 per cent Fe_2O_3 .

Fig. 8-8. The $K_2O-Al_2O_3-SiO_2$ system.

but melts only above 3200° F, and is in solid solution with MgO with lower percentages of Fe_2O_3 .

However, magnesia-bearing refractories contain other oxides, such as CaO and SiO_2 , which are also encountered in service; hence reactions occurring in the CaO-MgO- SiO_2 system shown in Figure 8-15 are important in the manufacture and use of most basic refractories. Many compounds, differing widely in refractoriness and stability are found in this system, their occurrence in refractories being governed largely by the lime-silica ratio; their desirability as a refractory constituent being governed by the intended service. Thus, aside from periclase (MgO) three of the most important compounds are forsterite ($2 MgO \cdot SiO_2$), monticellite ($CaO \cdot MgO \cdot SiO_2$) and dicalcium silicate ($2 CaO \cdot SiO_2$), with melting points of 3470° F, 2734° F (incongruent), and 3865° F, respectively. Generally, forsterite is the most desired bonding constituent in basic brick as it is stable and provides ample refractoriness and load-carrying ability. In high-magnesia refractories, forsterite is formed when lime is absent or the molecular ratio of lime to silica is less than 1. If, under these conditions silica is increased at the expense of MgO, low-melting liquids form; hence silica brick will react in contact with magnesite at about 2800° F, and magnesite must be added to some magnesia-deficient olivines used in forsterite-brick manufacture

to assure conversion of the silicates to forsterite on firing. With an increase in the lime-silica ratio to 1, the less-refractory monticellite is formed; thus lime is a flux to forsterite. However, monticellite, within limits, is desirable in promoting a bond or set in granular open-hearth-bottom refractories. With a further increase in the lime-silica ratio to 2, the refractory but unstable dicalcium silicate will form. When stabilized against dusting with small amounts of Cr_2O_3 , B_2O_3 , or phosphates, the intentional formation of this compound in some granular refractories is a convenient means of correcting either for excess lime which would hydrate, or excess silica which would produce an undesired amount of monticellite.

In general, the susceptibility to fluxing by iron oxides in this system increases as MgO is replaced by CaO and as Fe_2O_3 is replaced by FeO. However, those portions of the CaO-MgO- SiO_2 -FeO, or CaO-MgO- SiO_2 -Fe $_2$ O $_3$ systems which involve refractories are receiving further study.

The reactions involved in the manufacture and use of chrome-bearing refractories are numerous and complex, and are the subject of many continuing investigations. The major improvement in such refractories occurred about 1930 with the recognition of the fact that combinations of chrome ore and magnesite in any proportion

FIG. 8-9. The MnO-Al₂O₃-SiO₂ system.FIG. 8-10. The CaO-SiO₂ system.

FIG. 8-11. The FeO-SiO₂ system.FIG. 8-12. The FeO-Fe₂O₃-SiO₂ system.

produced refractories with greater thermal shock resistance, volume stability, and refractoriness under load than did either material alone. The added magnesia converts the low refractory silicates in chrome ore to forsterite, and also replaces FeO in the chrome spinel, thus maintaining the $RO-R_2O_3$ balance when FeO is oxidized to Fe_2O_3 , which readily occurs. Of primary interest, however, are those reactions occurring in service, particularly the growth or disruptive swelling occurring

on absorption of iron oxide by the chrome spinel under oxidizing conditions. It is not clear that this phenomenon is the major cause of the usual process of failure, which is characterized by a progressive peeling or flaking away of the hot face, as it is known that substantial growth can be induced in basic brick by suitable heat treatment without additions of iron oxide.

Further studies are being made in refractory systems involving Cr_2O_3 , MgO, Al_2O_3 , SiO_2 , CaO and iron oxides.

SECTION 5

SELECTION AND TESTING OF STEEL-PLANT REFRACTORIES

The ultimate goal in refractory selection is to achieve minimum overall operating costs per ton of steel. However, this is the universal endeavor of all phases of steel production, in some of which costs may be lowered only at the expense of refractories, as by harder driving of furnaces to increase the rate of production, or by a change to cheaper fuels which may increase refractory wear. Careful costs analyses may be required to determine which of the conflicting factors can best be sacrificed for maximum economy. Therefore, the specific aim of the refractories engineer is to obtain minimum refractory costs per ton of steel, but only those obtainable under operating conditions dictated by the above considerations. The successful selection of refractories requires a knowledge of refractory characteristics, a knowledge of service conditions and, based on experience, the ability to correlate the two in terms of performance. The importance of this work is attested by the fact that most steel companies now employ ceramic engineers and maintain laboratories devoted to quality control testing and research on refractories.

Information on refractory characteristics as revealed by standard A.S.T.M. tests is readily available from refractory suppliers or independent laboratories but, as indicated earlier, such data are often inadequate and

even misleading if not used intelligently. However, as it is always desired to establish correlations between performance in service and the simplest possible laboratory tests, the standard tests are an excellent starting point, and, because the range of variation in a given property is needed for proper correlation and quality control, the use of these tests in steel-plant laboratories is often the only means of determining such variations.

Obtaining information on service conditions is most important to the proper application of refractories. Systematic studies of used linings by chemical analysis, petrographic microscope, and various laboratory tests have clarified many of the mysteries as to the precise mechanism of failure of blast-furnace and open-hearth refractories, and have been responsible for some of the most significant advances in refractory practice and, also very important, in furnace design.

With information on refractory behavior and service conditions much of the guesswork can be eliminated from service trials, which of course, provide the final answer on refractory suitability. When failures are encountered in such trials they are generally indicative of the need for more fundamental refractory research, or, as often occurs, of changes in operating conditions from those on which the refractory selection was based.

SECTION 6

SPECIFIC USES OF REFRACTORIES IN STEEL PLANTS

Blast Furnaces and Stoves—For many years, blast furnaces were lined throughout with high-duty fireclay brick and, despite much recent experimentation with special grades of fireclay brick, the high-duty type still predominates. However, the present high-duty brick, reflecting the demands for improved performance sought with the use of premium-priced, high-fired, super-duty brick, are substantially improved in strength, resistance to abrasion and to disintegration by carbon monoxide, and in size uniformity, over those produced prior to 1950. The special, high-fired types of both high-duty and super-duty brick are now generally confined to the zone immediately below the wearing plates and in the bottom, where optimum advantage is taken of their superior density and strength, and where their rigidity and sensitivity to thermal shock, believed to be a factor in their somewhat disappointing behavior in stacks and hearth walls, is of small concern.

After many false starts and much experimentation, carbon brick or block prepared from petroleum coke or anthracite are now widely used in hearth walls from below the tuyeres to the bottom of the cooling staves. Carbon layers across the hearth bottom have been less successful, and where now installed in a few furnaces, these layers are generally keyed in and built in greater

thicknesses, up to 85 inches, to prevent flotation. Used above the mantle, carbon has proved vulnerable to oxidation, carbon disintegration or alkali attack, and it is questionable whether its use in this region will ever prove economical. In the bosh, thin carbon linings, externally water-cooled, are operating successfully, and this practice will probably increase, as fireclay linings endure only through excessive use of expensive water-cooled plates.

Refractory requirements in hot-blast stoves vary with the temperature of operation, design, gas cleanliness, and location in the stove. Combustion-chamber walls must resist deformation under load, spalling and alkali attack; and, with the exception of spalling, this is true of the top 10 or 20 feet of the checkers. Mechanical strength, density, and size uniformity are the chief requirements of the lower checkers. Although long service has been obtained with entire high-duty fireclay-brick linings, particularly in stoves with proper temperature control, many installations employ super-duty, semi-silica, or combinations of these brick in combustion chambers, domes, and the top checker courses.

Hot-Metal Mixers—Hot-metal mixers present some refractory problems, despite their comparatively low operating temperatures, which seldom exceed 2500° F.

The chief difficulties derive from excessive joint erosion resulting from a mechanical washing by the molten iron and corrosion by slag, and from designs which prevent streamlined construction at the spouts. These difficulties are accentuated if the mixer is fired to maintain temperature since, as the temperature of the slag is raised, it becomes more reactive on the lining. While linings of high-duty blast-furnace brick, mica schist, and occasionally sandstone may still be used, there is a definite trend to the more volume-stable, denser, hard-fired super-duty brick which have greatly prolonged lining life by minimizing joint erosion. Occasionally, in efforts to bring the lining life into balance, the critical areas around the spout may be lined with various types of high-alumina brick. Numerous trials of various types of basic brick have generally been disappointing.

Basic Open-Hearth Furnaces—The modern basic open-hearth shop probably employs a wider range of refractories than is found in any other high-temperature process. In the furnace itself, the types of brick that may be found include silica, semi-silica, all grades of fireclay, some grades of high-alumina, and nearly all kinds of basic brick. In granular or plastic form are found raw, calcined or clinkered dolomite, magnesite, special magnesite or dolomitic ramming mixtures, chrome ore, plastic chrome ore, and fireclay, silica, and basic mortars. With few exceptions, however, none of these refractories can be said to be securely established in a given application, as not only do requirements vary widely with the different practices in different shops, but changes are constantly being brought about by improvements in refractories and changes in fuels with accompanying changes in design. Currently, the overall trend in open-hearth refractories is toward increased use of basic refractories. Other trends and developments are revealed by a brief examination of refractories used in the various furnace parts, and in accessory equipment in the shop.

Hearth—Insulating brick or concrete may be used on the steel bottom followed by fireclay brick or basic brick (usually burned chrome) or both. Above this point the bottom may be (1) burned in entirely with dead-burned magnesite and slag, (2) rammed in completely with special sized and bonded magnesite or dolomitic-magnesia mixtures or (3) partially rammed with plastic chrome or the above ramming materials and covered by a burned-in layer of magnesite or clinkered dolomite. Until 1939, practice (1) only was employed, but (2) is currently more popular.

Front, Back and Endwalls—Front and backwalls were the first applications above the hearth to be converted from silica to basic refractories and now these are almost universally basic, of either chrome-magnesite or magnesite-chrome, burned or unburned. Basic endwalls followed later, and while now predominant, silica endwalls are still employed. Steel-encased magnesite-chrome unburned brick are most popular, and these walls are generally constructed with steel tie plates every 2 to 4 courses which are welded to the buckstays to prevent buckling.

Port Sidewalls—Port sidewalls at present are generally silica, except in a relatively small number of furnaces with basic ends, in which they may be constructed like endwalls, with suspended panels immediately above floor level.

Doors—An important development in open-hearth refractories has been the introduction of stud-type doors with plastic base refractory linings, usually chrome ore. Performance has generally more than justified the extra cost over brick-lined doors.

Roof—The supremacy of silica brick for open-hearth

roofs has not seriously been threatened by basic brick, although a few experimental all-basic roofs have shown considerable promise of eventual justification. With the trend to silica brick of ever lower impurity content to obtain maximum refractoriness, particularly as exemplified in the super-duty silica brick, some minor relief of the temperature limitations imposed on the open hearth by silica is obtained, but scarcely enough to offset the attractiveness of the far greater potentialities provided by basic brick. Basic roof experience thus far indicates the need for brick of improved volume stability in service and further improvements in roof design.

Uptakes—Uptakes, like port sidewalls are generally silica except in furnaces with basic ends, in which suspended basic construction is universally used. Occasionally super-duty fireclay brick or higher-alumina brick are employed in the lower zones.

Slag Pockets, Checker Chambers, and Flues—In basic-end furnaces, basic brick may extend down into the slag-pocket walls, but these are generally silica and sometimes fireclay brick. Checkers and checker chambers are generally built of high-duty brick, although super-duty or 60 per cent high-alumina brick may be used in the hottest sections, or in the fantail, and semi-silica brick may be used in the checker-chamber roof. Intermediate- and low-duty brick may be used in the flues and stack.

Basic Electric Steelmaking Furnaces—While electric-furnace refractories do not have to contend with the high-velocity gases common to the open hearth, they are often subjected to higher temperatures and in the latter part of the process, to reducing atmospheres. For this reason, more consideration has been given to more expensive refractories of higher melting points in the basic process. Sillimanite or mullite brick made of kyanite have been justified in many roofs in recent years, although silica is still generally relied on for the larger furnaces. Basic brick, either chrome-magnesite or magnesite-chrome, are generally used in the walls, and some experimentations have also been carried out with basic brick in the roof. The developments in hearth refractories have paralleled those of the open hearth.

Pouring-Pit Refractories—These refractories—sleeves, nozzles, stopper heads, and ladle brick—must withstand severe thermal shock and corrosion by molten steel and slag; and, with the exception of stopper heads, they generally do this best when made of the lower grades of refractory clays. There are two reasons for this apparent paradox, both based on the time factor. First, sleeves and nozzles are single-use refractories and seldom subjected to these conditions for much more than an hour; and ladle brick are necessarily cooled between each similar treatment. Second, each of these refractories, especially nozzles and ladle brick, during this short period must become pyroplastic to function to best advantage—nozzles to form a tight seal for the stopper, and ladle brick to seal and prevent accelerated wear of joints. Stopper heads obviously must remain hard and corrosion-resistant, and hence are made of refractory clay-graphite mixtures. However, to minimize the rate of wear of such low-refractory ladle brick and nozzles, these refractories must be dense. Because of the peculiarities of these requirements, other types of refractories have seldom proved satisfactory, and improvements have been gained more from a recognition of the foregoing facts and efforts to improve density, texture, and workmanship than from any substitution of other refractory types.

Soaking Pits—Soaking-pit linings must possess good load-carrying ability, high resistance to abrasion, and resistance to iron-oxide attack, particularly at the slag

line. Cover linings must be resistant to spalling as must the top of the pit walls, although mechanical abuse in this zone is the chief cause of deterioration. Several types of refractories for pit walls have been and are being employed, with a trend to the more siliceous types, such as sandstone, silica and semi-silica brick, and mica schist, as these generally meet the above requirements better, and require less maintenance, than do fireclay brick. Slag-line maintenance remains a problem, and although basic brick are usually employed, comparable service has been obtained with 70 per cent alumina brick with resultant savings from lower first cost. Super duty brick, semi-silica brick, castables and plastics have also come into use, particularly for cover linings, where a definite trend toward the monolithic refractories has developed. Wide variations in operating conditions are chiefly responsible for the variety of refractories in current use, as each plant presents individual refractory problems.

Heating Furnaces—Heating furnaces include a variety of types and service conditions, but refractory requirements are generally met by fireclay brick. Spalling resistance is needed in most furnaces however, and recognition of this has led to greater use of super-duty and semi-silica brick in recent years, particularly in suspended and sprung arch roofs, and in the walls of heating zones of continuous slab-heating furnaces. More recently, rammed or cast monolithic walls and roofs have been used with considerable success. The problem of refractories for solid hearths in such furnaces has been eased but not eliminated by basic brick, rammed

basic plastics, or high-alumina brick. Burner-block difficulties have been greatly improved through the use of super-duty, high-alumina, or sillimanite block, either prefired or rammed. In many low-temperature heat-treating furnaces advantage can be taken of the low heat capacity and insulating value of light-weight fireclay brick.

Chapter 9

ADDITION AGENTS USED IN STEELMAKING

Definitions—Steelmaking involves the deliberate addition of various chemical elements to the molten metal to effect several desirable ends. These ends may include deoxidation of the molten metal to the desired degree, control of grain size, improvement of the mechanical and physical properties and corrosion resistance of the steel, increase of the response of the steel to subsequent heat treatment, or attainment of other specific effects that are discussed elsewhere in this book. Originally, the chemical element it was desired to incorporate into the steel was added to the bath in the form of an alloy that consisted principally of iron but was rich in the desired element. Such alloys, because of their high iron content, became known as *ferroalloys*, and most of the available types were produced in the iron blast furnace. Eventually, the production of alloys for steelmaking purposes began to be carried out in electric-reduction and other types of furnaces as well, and a number of alloys now produced contain relatively little iron. For this reason, the term *addition agent* is preferred to describe any of the materials added to molten steel for altering its composition or properties; under this definition, the ferroalloys form a special class of addition agents.

The more common addition agents definitely in the ferroalloy class include alloys of iron with aluminum, boron, calcium, chromium, columbium, manganese, molybdenum, nitrogen, phosphorus, selenium, silicon, tantalum, titanium, tungsten, vanadium, and zirconium. Some of these chemical elements and others are available in addition agents that are not ferroalloys, as well as in almost pure form; these include relatively pure metals such as aluminum, calcium, cobalt, copper, manganese and nickel; oxides of molybdenum, nickel and tungsten; carbon, nitrogen and sulphur in various forms; and alloys consisting principally of combinations of two or more of the foregoing elements. The more important of the addition agents (including ferroalloys) will be discussed individually later in this chapter. Although work on the use of rare-earth alloys is in progress, the results reported thus far are still under investigation and the use of such alloys in steelmaking will not be discussed here.

Use of Addition Agents—Addition agents may be added with the charge in the steelmaking furnace, or in the molten bath near the end of the finishing period, or in the ladle or in the molds. Timing of the alloy additions is dependent on the effect of the addition on the temperature of the molten metal, ease with which specific addition agents go into solution, susceptibility of a particular addition agent to oxidation, and formation and elimination of reaction products.

Economy in manufacture of alloy steels requires consideration of the relative affinity of the alloying elements for oxygen as compared with the affinity of iron for oxygen. For example, copper, molybdenum, or nickel may be added with the charge or during the working of the heat and are wholly recovered. Chromium and manganese, because they are easily oxidized, should be added late in the heat and all or part of these two may be added in the ladle. In open-hearth practice, easily

oxidized materials such as aluminum, boron, titanium, vanadium, and zirconium are normally added in the ladle in order to minimize oxidation losses.

It is often necessary to preheat the ferroalloy to avoid undue chilling of the bath. When large additions are made entirely to the bath, time must be allowed for the molten steel to be reheated to the desired temperature before tapping. The ferroalloy additions may be split between the furnace and the ladle, and in cases where excessive chilling of the metal in the ladle is to be avoided, the lower alloy recovery in the furnace must be accepted.

The agents to be added to the bath should be lump size (say 5 inches) in order to penetrate the slag easily. For ladle additions, the alloy should have a maximum size of approximately 2 inches in order to assure rapid solution.

Storage Facilities for Addition Agents—From the standpoint of material handling and of conservation and identification, it is advisable to store addition agents in properly designed bins in which they are protected from the weather. The location and design of bins should make the contents quickly available and with a relatively low handling cost. All bins should provide identification of the contents since confusion may be costly due to failure to meet specified chemical composition of the finished steel. Certain addition agents are more easily broken on handling than others, and caution should always be exercised to avoid production of fines.

COMPOSITIONS OF COMMON ADDITION AGENTS

Ferromanganese is the most important of the ferroalloys used in steelmaking. **Standard ferromanganese** contains 74 to 82 per cent manganese, and contains not more than 1.25 per cent silicon, 0.35 per cent phosphorus, 7.50 per cent carbon, and 0.05 per cent sulphur. **Low-phosphorus ferromanganese** suitable for addition to acid open-hearth steel should not contain over 0.10 per cent phosphorus. **Low-carbon ferromanganese** is used when it is important to limit the amount of carbon entering the steel from the ferromanganese addition. This low-carbon product is available in several grades containing increasing amounts of carbon, e.g., 0.07 per cent, 0.10 per cent, 0.15 per cent, 0.30 per cent, 0.50 per cent, and 0.75 per cent (all maxima), and the lower the carbon content the higher the price per pound. All of the foregoing grades of low-carbon ferromanganese contain 80 to 85 per cent manganese. **Medium-carbon ferromanganese** contains a maximum of 1.5 per cent carbon and 80 to 85 per cent manganese. If low-carbon and medium-carbon ferromanganese are used as bath additions (to the furnace) such additions should be made after the bath has been deoxidized.

Silicomanganese is used by some open-hearth furnace operators as a furnace addition to **block the heat** (retard the oxidizing reactions taking place in the furnace toward the end of the finishing period) because of the shorter holding time required from time of addition to tap, as compared with the use of ferrosilicon followed by

ferromanganese. Silicomanganese contains 65 to 68 per cent manganese, 18 to 20 per cent silicon, and a usual maximum of 1.5 per cent carbon.

Spiegeleisen is available in grades containing 16 to 28 per cent manganese, with the carbon content not over 6.5 per cent. The silicon content of spiegeleisen is from 1.0 to 4.5 per cent. A grade known as *silicospiegel* contains 25 to 30 per cent manganese, 2 to 3 per cent carbon, and 7 to 8 per cent silicon. Spiegeleisen (usually called *spiegel*) is used as an addition to the bath and in the refining or last stage of the open-hearth process.

Ferrosilicon—The low-silicon grades of ferrosilicon, which usually start at 10 per cent silicon and ordinarily do not exceed 17 per cent silicon, generally are blast-furnace products, and contain 1.50 per cent maximum carbon. **Electric-furnace ferrosilicon**, made by an electric-furnace process, is graded according to silicon content. The principal grades contain, respectively, 25 per cent, 50 per cent, 75 per cent, 85 per cent, and 90 to 95 per cent silicon. The grades containing the most silicon can be obtained with special low aluminum content. The 50 per cent silicon grade is by far the most widely used, and is employed chiefly as a ladle addition. The 10 to 15 per cent and 25 per cent silicon grades are those usually used in the open-hearth furnace for blocking, although other grades are also used, and may also be used as deoxidizers added prior to addition of other more expensive alloys.

Ferrochromium, containing 65 to 72 per cent chromium and a maximum of 2 per cent silicon, is classified into grades by carbon content. The respective grades contain 0.06 per cent, 0.10 per cent, 0.15 per cent, 0.20 per cent, 0.50 per cent, 1.00 per cent, and 2.00 per cent carbon, along with the most commonly used and cheapest grade containing 65 to 69 per cent chromium and 4.50 to 8.50 per cent carbon. Ferrochromium containing the higher amounts of carbon is used as a furnace addition. As in the case of ferromanganese, the alloys of lower carbon content are the more expensive. Briquettes of ferrochromium in which are incorporated chemical reagents to provide exothermic reactions permit chromium to be added to the ladle in this form without an undue chilling effect.

Ferrovandium, containing 35 to 55 per cent vanadium, usually is added to killed steel in the ladle.

Ferromolybdenum, containing 55 to 75 per cent molybdenum, is used where the higher molybdenum contents are desired. For lower molybdenum contents, molybdenum oxide or calcium molybdate may be used. All are furnace additions.

Ferrotitanium available in the following grades generally is used as a ladle addition: regular grade containing 40 per cent titanium and a maximum of 0.10 per cent carbon; low-carbon grade containing 25 per cent titanium and a maximum of 0.10 per cent carbon; and a high-carbon grade containing 15 to 19 per cent titanium and 6 to 8 per cent carbon.

Zirconium is obtained from one alloy containing 12 to 15 per cent zirconium, 39 to 43 per cent silicon, and a maximum of 0.20 per cent carbon; or another containing 35 to 40 per cent zirconium, 37 to 52 per cent silicon, and a maximum of 0.50 per cent carbon. These zirconium alloys generally are added in the ladle.

Ferrophosphorus in two grades containing, respectively, 17 to 19 per cent and 23 to 26 per cent phosphorus, usually is added in the ladle.

Nickel, obtained in the forms of sheared electrolytic cathodes or as ingots produced from remelted cathodes, both containing a minimum of about 99 per cent nickel, is used as a furnace addition. Little or no nickel is lost through oxidation when it is added to the bath, so nickel

steels are made by charging nickel-steel scrap and adding metallic nickel after the charge has been melted completely. Nickel oxide is sometimes used in conjunction with reducing slags in the electric furnace as a source of metallic nickel.

Copper usually is added to the bath in the form of virgin copper pigs or as scrap copper. It also can be recovered, with little or no loss, from copper-bearing steel scrap in the initial furnace charge.

Aluminum usually is added in the form of secondary aluminum having an aluminum content of from 85 per cent upward. It generally is used in the form of shot for addition to the ingot mold, or as shot or bars for addition to the ladle. In special cases, as when used for the deoxidation of small ingots, the metallic aluminum content of the addition may be as high as 97.5 per cent. Limitations are placed on the copper content of aluminum used in steelmaking operations, and generally it is not allowed to exceed 4.5 per cent.

Cobalt in metallic form (97 to 99 per cent pure) is usually added to the furnace in the form of shot or rondelles in the manufacture of high-speed steels, permanent-magnet steels and other special steels in the electric furnace.

Ferrocolumbium, containing 50 to 60 per cent of columbium and up to 8 per cent silicon with a maximum of 0.40 per cent carbon, is usually added through the reducing slag in electric furnaces in the production of austenitic stainless steels of the chromium-nickel type and alloys for use at high temperatures.

Ferroselenium, used for the addition of selenium to stainless steels to improve their machinability, is added to the ladle during the tapping of electric-furnace heats. It contains 50 to 60 per cent of selenium.

Tantalum for steelmaking purposes is available as ferrotantalum-columbium, which has a content of approximately 20 per cent tantalum, 40 per cent columbium and a maximum of 0.30 per cent carbon. It can be used as a replacement for ferrocolumbium in some cases.

Tungsten, used principally in the manufacture of high-speed tool steels in electric furnaces, is available from ferrotungsten, the standard grade of which contains 70 to 80 per cent of tungsten and a maximum of 0.60 per cent of carbon. Tungsten is also obtained from oxide forms such as scheelite and calcium tungstate.

Sulphur as required by specification is added to the ladle in the form of such addition agents as flowers of sulphur, stick sulphur, iron sulphide, or less often as manganese sulphide, sodium sulphide, etc.

Carbon—For raising the carbon content of the steel during tapping, additions may be made to the ladle in the form of coke, anthracite coal, graphite, or petroleum derivatives. It is desirable that such additions be low in sulphur and high in carbon.

"Hardenability Intensifiers"—A number of ferroalloys are designed to increase the hardenability of steel when added in relatively small amounts. They usually contain boron together with one or more of the following elements: silicon, titanium, vanadium, zirconium, aluminum, manganese, calcium, or other deoxidizers or denitrifiers.

The foregoing brief descriptions of addition agents summarize only the principal sources of the various elements for the manufacture of steel, with some reference to the manner in which most of them are used. Specific reasons and the manner for the use of individual addition agents, or combinations of them, are discussed in other chapters describing the several steelmaking processes and the properties and heat treatment of AISI alloy steels, stainless and heat-resistant steels, and tool steels.

Chapter 10

SCRAP FOR STEELMAKING

Scrap consists of the by-products of steel fabrication, and worn out, broken or discarded items containing iron or steel. It is one of the two principal sources of metal in steel-making; the other principal source is iron from the blast furnaces, either molten as it comes from the blast furnace ("hot metal") or in solid pig form. Scrap is of great practical value. Every ton of scrap consumed in steelmaking is estimated to displace and conserve for future use $3\frac{1}{2}$ to 4 tons of other natural resources including iron ore, coal and limestone. On the average, the steel industry consumes about equal quantities of scrap and blast-furnace iron. According to recently published figures of the American Iron and Steel Institute, the steel industry consumes an average of about 54,000,000 tons of iron and steel scrap in producing 100,000,000 net tons of ingots and steel for castings. The metallic charge for an open-hearth steelmaking furnace consists, on the average, of about one-half steel scrap and one-half molten iron (hot metal). Bessemer converters and other pneumatic processes employ molten iron (hot metal) almost exclusively; while the electric furnace usually is charged almost entirely with cold scrap. Table 10—I summarizes the consumption of scrap and blast-furnace iron by the several steelmaking processes and the blast furnace during 1953.

Table 10—I. Consumption of Scrap and Hot Metal and Pig Iron by Steelmaking Processes and Blast Furnaces During 1953*

Process	Consumption (Net Tons)	
	Scrap	Hot Metal and Pig Iron
Bessemer	218,998	4,249,149
Open-Hearth	48,698,391	61,105,870
Electric	7,327,627	134,144
Blast Furnace	5,005,873	21,456

* American Iron & Steel Institute

Types and Sources of Scrap—Scrap iron and steel may be classified as originating from two sources: home scrap produced as unsalable products unavoidably resulting from steelmaking and finishing operations, and purchased scrap.

Home scrap (also called "revert scrap") includes such items as pit scrap; ingots too short to roll; rejected ingots; ingot crops; crop ends from blooms and billets; shear cuttings from trimming flat-rolled products to accurate size; products irrecoverably damaged in handling or finishing; ends cut from bars, pipe or tubing to bring them to standard or exact ordered length; turnings from machining operations, and so on. Bloom crops constitute the largest single item of home scrap. Advances in steelmaking techniques have tended to reduce the

proportion of the ingot that must be cropped. While this has reduced the quantity of home scrap, it has resulted in a higher proportion of steel from the ingot being shipped to consumers in the various forms of finished steel. This has partially offset the loss in home scrap by increasing the proportion of prompt industrial scrap, discussed below.

In general, according to the source referred to above, about 31,500,000 net tons of home scrap results from the manufacture of 100,000,000 net tons of steel ingots (and steel for castings—a small percentage of the whole) and the processing of this steel into finished products.

Purchased scrap must be used to the extent of 22,500,000 net tons to supplement the 31,500,000 tons of home scrap to provide the 54,000,000 tons of iron and steel scrap needed to produce the hypothetical 100 000,000 net tons of steel used here as a basis for discussion. Purchased scrap is divided into two general classifications: (1) dormant scrap and (2) prompt industrial scrap.

Dormant scrap comprises obsolete, worn out or broken products of consuming industries. Typical examples of dormant scrap are: discarded steel furniture, washing machines, stoves and other outdated consumer goods; beams, angles, channels, girders, railings, grilles, pipe, etc., arising from the demolition of buildings; useless farm machinery; obsolete, broken or damaged industrial machinery; old ships; railroad rails and rolling stock that have outlived their usefulness; wrecked automobiles, and so on. This type of scrap, because of its miscellaneous nature, requires careful sorting and classification in segregated lots to prevent the contamination of steel in the furnace with unwanted chemical elements that may be present in some of the scrap. It should also be of such physical size as to facilitate handling and loading into charging boxes. The need for proper classification and preparation of dormant scrap is emphasized by the existence of 75 different specifications covering various grades of scrap for use in blast furnaces, acid and basic open-hearth furnaces, electric furnaces, bessemer converters, gray-iron foundries and elsewhere. In addition, the Association of American Railroads has forty-five specifications applying to scrap of railroad origin. These all have been prepared to facilitate proper classification of scrap for different uses.

Prompt industrial scrap is generated by steel consumers in making their products. It may consist of the unwanted portions of plate or sheet that has been cut or sheared to the desired final size and shape, trimmings resulting from stamping and pressing operations, machine turnings, rejected products scrapped during manufacture, short ends, flash from forgings, and other types of scrap. Prompt industrial scrap can usually be identified easily as to source and composition, provided that proper plans for segregation are in effect in the consumer's plant, the scrap dealer's yard, and in the steel plant.

Of the 33,000,000 tons of purchased scrap actually con-

sumed in 1953, about 9,500,000 tons originated as prompt industrial scrap in metal-working factories in the processing of finished steel and of iron castings into capital and consumer goods. About 5,000,000 tons came from auto-wrecking operations, 4,000,000 tons from the railroads, 2,000,000 tons from farms, and the remainder from shipbreaking, public utilities, refineries, collectors, and demolition—with demolition the major general source. In a typical month during that year, open-hearth furnaces used 56 per cent of all purchased scrap, 72 per cent of the home scrap, and 83 per cent of the pig iron. Electric furnaces accounted for 6 per cent of scrap and pig iron combined. Blast furnaces used 8 per cent of all purchased scrap.

Physical Preparation of Scrap—Scrap is classified according to its physical size and chemical composition. Pieces too large to be accommodated by charging-machine boxes must be cut into satisfactorily smaller sizes; shears, flame-cutting, impact devices and other means may be used, depending upon the type of scrap being handled. Sometimes, very large pieces of scrap that cannot pass through the furnace doors may be charged into an open-hearth furnace by overhead crane when the furnace roof is off during rebuilding. Sheet shearings, punchings and similar types of relatively thin and usually small pieces of scrap may be compressed into block-like bundles in specially-designed hydraulic baling presses; since about half of the steel rolled in the United States at present is in the form of relatively thin flat-rolled products, large quantities of scrap require baling.

Assuming that scrap has been properly sorted with respect to its chemical composition, as discussed later, the primary purpose achieved by the proper preparation of scrap is to increase the amount of scrap that can be loaded at one time into a charging box for placing the scrap in the steel-producing furnace. The denser the load in the charging boxes, the fewer the number of boxes that need to be loaded, transported and their contents dumped into the furnace, and the less the time consumed in charging the furnace. Delays in charging can result in considerable loss of steel production.

The prime grade of purchased scrap for production of open-hearth steel must be at least $\frac{1}{8}$ -inch thick, no more than 18 inches wide, nor more than 5 feet long. Electric furnaces require purchased scrap of smaller dimensions ranging in size from 3 feet down to punchings; further details relating to scrap for electric-furnace melting are given in Chapter 16. Short lengths of turnings are the preferred form of scrap for blast-furnace use.

Chemical Composition of Scrap—Certain chemical elements are desirable constituents of scrap for steel-

making, especially when used in electric furnaces, as discussed in Chapter 16. In general, however, scrap for all of the steelmaking processes should be free from unknown and unwanted elements referred to as "tramp alloys." The increasing use of alloy steels of many compositions has aggravated the tramp alloy problem since more and more purchased scrap may be expected to include unidentified alloy steels.

The segregation of home scrap according to its chemical composition is relatively simple. Purchased scrap, especially dormant scrap, presents some problems since a large percentage of it is of unknown origin and composition. While it would be impossible to chemically analyze each individual piece of the huge amounts of dormant scrap consumed every year, the chemical analysis of selected samples of individual lots sometimes is employed by steel plants in the classification of scrap. Spectrographic analysis sometimes is employed instead of chemical analysis because it is more rapid; however, both are relatively time-consuming and expensive and both require careful selection and preparation of samples. Some less costly but less accurate tests are commonly used; these include magnetic tests, spark tests, spot tests and pellet tests as described briefly in Chapter 16.

When the chemical composition of scrap is known, the scrap can prove to be a valuable source of alloying elements needed in the production of alloy steels. Full advantage is taken of this source in the production of alloy steels in the electric furnace. In the open-hearth furnace, however, the preponderance of production consists of carbon and low-alloy steels and, in general, alloying elements in scrap are a source of trouble.

Tin, copper, nickel and other elements present in scrap will alloy readily with steel and, in many instances, render it unfit for its intended use. Relatively small amounts of these metals can contaminate an entire heat of steel. Tin and copper in certain ranges of composition cause brittleness and bad surface conditions in steel. Nickel and tin not only contaminate heats into which they may be unintentionally introduced, but may deposit a residue in the furnace that is absorbed by successive heats with resultant contamination. Zinc volatilizes in steelmaking furnaces and, by reacting with the hot refractories, causes rapid deterioration of brick work. Lead is extremely harmful to furnace bottoms and refractories and, if present in sufficient quantities, may cause furnaces to break out by penetrating joints or cracks in the bottom to form channels that may be followed by molten steel. The foregoing examples represent some of the difficulties caused by only a few of the chemical elements that may enter steel from poorly prepared or carelessly classified scrap.

Chapter 11

THE MANUFACTURE OF SPONGE IRON AND WROUGHT IRON

SECTION 1 SPONGE IRON

Sponge iron provided the main source of iron and steel for many centuries before the blast furnace was developed around 1300 A.D. It was produced in relatively shallow hearths or in shaft furnaces, both of which used charcoal in the double role of a fuel to supply heat and a chemical reducing agent to reduce the iron from the ore by combining carbon from the fuel with the oxygen from the ore. The product of all of these smelting processes was a spongy mass of coalesced granules of nearly pure iron intermixed with considerable slag. Usable articles of wrought iron were produced by hammering the spongy mass while still hot from the smelting operation, to expel most of the slag and compact the mass. All of the methods whereby wrought iron can be produced directly from the ore are called **direct processes**. After development of the blast furnace, which made large quantities of iron having a high carbon content available, wrought iron was produced by refining this high-carbon material; because two or more steps were involved in the processes employed, they came to be known as **indirect processes**.

Direct methods are still in use among certain peoples, and, indeed, have never been wholly abandoned even by the most advanced nations. The ease with which iron ores are reduced makes the direct process appear enticingly simple and logical. The reduction takes place at low temperatures and absorbs little heat, some of the reactions actually being exothermic.

For the past hundred years, sponge iron itself has found increasing use in various industrial processes, other than in the manufacture of wrought iron. Since the iron produced in sponge form is of high purity, it is used extensively in the chemical industry as a strong reducing agent and is chemically much more active than steel or iron in the form of millings, borings, turnings, or wire, because of its porous or spongy nature. Sponge iron may be produced as a granular material or as a sintered mass, depending upon the methods of manufacture. In the granular form, in which it is commonly known as **powdered iron**, it is used in the manufacture of many useful articles by the techniques of **powder metallurgy**, in which the powders are first compacted by pressure alone into the approximate shape of the finished article; the compact is then "sintered" at a temperature ranging roughly between 1800° and 2000° F in furnaces provided with a protective atmosphere to prevent oxidation. The sintered articles are then pressed or otherwise processed to give them their final accurate shape.

It may be mentioned that iron powders are produced,

not only by direct reduction of iron ores or oxides using solid carbonaceous reducing agents (coal, coke or charcoal), but also by electrolytic processes, by thermal decomposition of iron carbonyl which has the chemical formula $\text{Fe}_2(\text{CO})_9$ and by the reduction of iron ore or pure oxides with various gaseous reducing agents such as carbon monoxide or hydrogen.

In connection with the direct reduction processes mentioned, it is interesting to note that dry iron oxides (hematites or magnetites), in the presence of a small excess of reducing substance, form dark-gray porous masses having the same size and shape as the original lumps or particles when reduced at temperatures below 1650° F (900° C), and that a temperature of 1740° to 1830° F (950° to 1000° C) is necessary to effect complete reduction in a reasonable length of time, unless the ore is of a selected particle size. At 1830° F (1000° C) the product begins to sinter, and forms a pasty, porous mass at 2190° F (1200° C). At 2370° F (1300° C) the mass absorbs carbon rapidly, if the latter is present, and begins to fuse, though the upper melting (completely liquid) point of pure iron is 2785° F (1530° C).

In addition to the commercial production of sponge iron by direct reduction for the foregoing purposes, much effort and expense has been incurred for a long period of time in an effort to discover some practicable direct-reduction process that would produce iron economically for use in steelmaking operations, thus eliminating, at least partially, the need for blast-furnace pig iron. Although iron ore can be reduced directly with relative ease on a small scale, no commercially useful process has been developed to date that shows any promise of supplanting the blast furnace as the chief source of iron units for steelmaking.

The attempts to develop a direct process for manufacturing iron and steel that could compete with the indirect processes now in use have embraced practically every known type of apparatus suitable for the purpose, including pot furnaces, reverberatory furnaces, regenerative furnaces, shaft furnaces, rotary and stationary kilns, retort furnaces, electric furnaces, and various combination furnaces. Many different kinds of reducing agents have also been tried, such as coal, coke, graphite, distillation residues, fuel oil, tar, producer gas, coal gas, water gas and hydrogen. Practically all of these processes have been abandoned, and it is unnecessary to give details of them here, especially since adequate descriptions are to be found in other works on this subject.

While the process of producing low-carbon iron direct from ore is theoretically very attractive and appears

more logical than indirect processes (in which high-carbon pig iron is first produced and then purified to make iron and steel), direct processes have failed in competition with indirect methods. Apparently, the chief reasons why the direct process resists all efforts to establish it are these: (1) The ore must be a very rich one. (2) The ore must be finely divided and intimately mixed with or carefully placed over the reducing agent. (3) So far, no practical plan has been evolved whereby the ore and reducing agent may be mixed in proper proportions to leave no excess of either. If an excess of

the former is permitted, the process is wasteful of ore, while in the presence of an excess of the latter, the iron is obtained at a low temperature in sponge or pasty form which is hard to handle. If produced at a higher temperature, phosphorus in the ore will be reduced and the carbon absorbed from the fuel, giving a very impure metal, little better than pig iron. Sulphur, except when an excess of calcium oxide is present, is readily absorbed by the metal and cannot be removed except under highly reducing conditions such as prevail in the blast furnace or an electric furnace.

SECTION 2

DIRECT PROCESSES FOR MAKING WROUGHT IRON

Historical Background of Direct Processes—From about 1350 B.C. to 1300 A.D. all of the iron wrought into tools and weapons was produced directly from ore. Reduction of iron ore was carried out in a relatively simple manner using charcoal as fuel. In the earliest times the operation was carried out in crude hearths which eventually were superseded by furnaces of various designs having a strong family resemblance.

In the first smelting hearths or furnaces, natural draft alone supplied the air for combustion. Later, it seems to have been the practice to construct the hearth on a hillside or at the base of a cliff facing in the direction of a prevailing wind (Figure 11-1). A wind of suitable di-

FIG. 11-1. Schematic representation of an early smelting furnace, built on a hillside to take advantage of the direction of prevailing winds to supply a gentle blast. Actual discovered remains of similar furnaces indicate that the hearth of such furnaces may have been relatively shallower and greater in area in proportion to their height.

rection and velocity could be led into the burning fuel bed through an opening in the hearth or furnace wall to provide the air blast required to produce strong combustion of the charcoal fuel. Still later, devices for blowing air into the fuel bed were developed to make the process independent of wind and weather. These devices ranged all the way from mouth-blown hollow reeds, through foot-operated bladders of animal skins, foot-operated bellows, hand-operated bellows, and air-blowing devices operated by treadmills and water wheels. Another device somewhat widely used was the *trompe*, which made use of the aspirating effect of a falling column of water inside a tube, to draw air in

through holes in the sides of the tube near its top, and expel the air into a closed chamber at the bottom; the air was piped from this chamber to the furnace (see Figure 11-2).

FIG. 11-2. (Right) Schematic representation of the operation of the *trompe* for utilizing the principle of aspiration to provide air blast for smelting furnaces. (Left) Sketch of external appearance of a *trompe*. The cross-section of the vertical column was more commonly round than square.

In view of the many centuries in which the direct process was used, it is to be expected that many different methods and types of apparatus would have been developed. Little is known of the furnaces in use prior to the eighteenth century, but the majority were of the hearth type, while the remainder were of the shaft type and may be compared to small blast furnaces, as will be discussed later. While these furnaces might, and did, differ widely as to form, size, and materials of construction, the fundamental metallurgical principles were the same in all. The ore, in lumps or in more or less finely divided form, was mixed with charcoal and charged into the furnace. Charcoal served the triple purpose of (1) a fuel to supply heat, (2) a reducing agent, and (3) a protector to shield the hot reduced metal from the oxidizing influences of the air.

The Catalan Process—The Catalan hearth, as the furnace used in this process was called, was anywhere from 20 inches square and 16 inches deep to around 30

inches by 40 inches and something over two feet deep. The nozzle or tuyere, through which the blast was blown into the furnace, was placed about 9 inches from the bottom in the smaller hearths and about 15 inches from the bottom in the larger hearths. The hearth was filled to the level of the tuyere with charcoal, on which was piled lump ore together with charcoal. These materials were placed so as to form two separate columns, the charcoal against the tuyere side of the hearth, and the ore against the other side (Figure 11—3). A gentle

FIG. 11—3. (Above) Representation of a Catalan hearth or forge used for smelting iron ore up until relatively recent times. (Below) Cross section showing method of charging fuel and ore in the Catalan hearth, and approximate position of the nozzle supplied with air by a bellows.

blast of air was applied at first and the carbon monoxide, formed by combustion of the charcoal, passed preferentially through the open pile of lump ore. The ore was reduced to metallic iron when the oxygen in the iron oxide of the ore combined with the carbon monoxide to form carbon dioxide. The waste gases escaped at the top of the charge. Charcoal (along with fine ore) was added at regular intervals to replace that consumed in combustion. After about two hours, the lump-ore column was gradually pushed downwards and the temperature of the hearth was raised by increasing the blast. As successive portions of the ore became reduced, they were pushed nearer the tuyere where the hearth was hottest. By the time the ore had reached the hotter regions, it was largely reduced to the metallic state.

The unreduced portion of the lump ore, along with part of the fine ore added periodically with charcoal, formed a siliceous slag of high iron content with the gangue (waste material). The metallic iron resulting from reduction of the ore became pasty at the temperatures existing near the tuyere, to form a coherent loup

or bloom. After as much as possible of the ore had been reduced, the bloom was pried out of the hearth and hammered into bar form.

The American Bloomery—Among the variations of the process just described was the **American Bloomery Process** which was very similar to the Catalan process, differing from it chiefly in the fact that ore in a fine state, instead of in lumps, was mixed with charcoal to form the charge. The American bloomery represented the highest development in the simple hearth type of furnace for producing wrought iron. The bellows supplying the blast was operated by a water wheel or steam engine. The hearth was provided with a water-cooled metal bottom-plate, and cast-iron plates lined the sides. These hearths, rectangular in shape, were about 2 feet deep and 3 feet wide, and were surmounted by a tall chimney in the form of a truncated pyramid for carrying off the hot waste gases. The blast was heated (to save fuel) by passing the air through cast iron pipes around which the hot waste gases passed on their way from the furnace to the opening of the stack. Usually, bloomeries were open in front like an open fireplace, with the tuyere placed either at one side or at the back, about 20 inches above the bottom. Charcoal was first put into the hearth, the blast turned on, and when the fire was burning well, some ore was spread on the charcoal. Thereafter, charcoal and ore were added alternately until a sufficient amount of metal had collected upon the bottom. Then the iron, in a pasty mass and mixed with much slag, was removed from beneath the fuel bed with bars and tongs and hammered into a bloom. The last wrought iron to be produced by the bloomeries in this country was made in 1901.

The Stuckofen (High Bloomery)—The stuckofen or old high bloomery, variations of which appear to have been called salamander furnace, wolf furnace, wolf oven, wulf's oven and luppenofen or loup furnace, evolved from the Catalan type of hearth furnace. The earliest recorded types of these furnaces were in territories included in pre-World War II Germany (Nassau, Siegen, Saxony) and in parts of Austria, Belgium and the Netherlands. It was a furnace, 10 to 16 feet high, having a round, elliptical or rectangular cross section (greatest cross-sectional dimension, about 3 to 4 feet). One or two tuyeres supplied the blast, located somewhat over a foot above the hearth. Fuel and ore were charged into the top of the furnace, being replenished from time to time as smelting proceeded. A drawing hole was provided in the wall at the bottom of the shaft for extracting the blooms. This hole was closed by brick or stone work that was torn out each time a bloom was removed, after which the hole was again closed. Charcoal was the only fuel used.

The furnace called the wolf oven has been described as lower than the stuckofen, perhaps 6 to 7 feet in average height. Intermediate in size, between the wolf oven and the stuckofen, are the *blasofen* and *bauernofen*. The *bauernofen* corresponds to the *osmund furnace* (about 8 feet high) used in Sweden (a similar type was used in India). A type of furnace which originally resembled and was operated like the stuckofen, and was later adapted to produce either blooms of low-carbon wrought iron or molten, high-carbon iron, resembled a crude blast furnace and was termed *blauofen*, *blau furnace* or *blue furnace*.

The stuckofen may be considered as the forerunner of the modern blast furnace which produces only liquid, high-carbon iron. Liquid high-carbon iron often was produced in the stuckofen, intentionally or otherwise. This occurred when the reduced iron was in contact with hot fuel away from the blast long enough to absorb

sufficient carbon to reduce its melting point to where it would become liquid. The height of the furnace made this possible, especially if the operating temperature was high enough. A *flussofen* was strictly a primitive blast furnace intended only to produce molten, high-carbon iron. It may be said in general that the furnaces for producing molten high-carbon iron developed gradually from the early hearths in which only wrought iron was produced. The development consisted in gradually increasing the height of the furnace and introducing the charge at intervals through the top. These higher furnaces, distinguished as a class from the Catalan type of hearth or bloomery, were termed shaft furnaces. The

modern blast furnace is a shaft furnace, gradually evolved from the *stuckofen* and *flussofen*. In its early days it was called a **high furnace**, from its German name, *hochofen* (French: *haut fourneaux*). It is designed solely to produce molten iron and operates continuously, in that the solid raw materials (ore, coke and limestone) are charged at the top at regular short intervals, and the molten iron and slag which collect in the hearth are tapped out at longer intervals. Modern blast furnaces are commonly 80 to over 100 feet high, the larger furnaces producing well over 1000 tons of molten iron per day. The development of the modern blast furnace will be described in Chapter 12.

SECTION 3

INDIRECT PROCESSES FOR MAKING WROUGHT IRON

After furnaces which produced molten high-carbon iron became commonly employed in Europe, part of their product was used to produce iron castings by pouring the liquid metal into molds of the desired shape. Such cast iron had limited usefulness, since it was inherently hard and brittle due to its high-carbon content and the presence of other elements that entered the iron during reduction of the iron ore. It was not malleable, that is, it could not be shaped at any temperature below its melting point by either hammering or rolling.

In order to utilize the high-carbon product of these furnaces for making forged or wrought articles, it was necessary to develop purifying processes that would remove the excess carbon, manganese, silicon, etc., from the impure iron to produce relatively soft, malleable wrought iron that would have the same general composition and characteristics as the iron formerly produced directly from the ore in the Catalan and similar processes. As might be expected, a very great number of methods were developed in different localities. Two types of processes eventually became prominent: the charcoal-hearth processes and the puddling process.

Since the production of wrought iron from ore by any of these processes involved two separate steps: (1) reducing the ore to make pig iron and (2) remelting and purifying the pig iron to make wrought iron, they were referred to as **indirect processes**.

Some of the most widely used charcoal-hearth processes for purifying pig iron are described below (the Walloon, South Wales and Lancashire processes).

Walloon Process—Just how, when, where, and by whom wrought iron was first produced from pig iron is unknown, though it is probable the process originated in Belgium. The first attempts were, no doubt, made in the forge or on a hearth such as those already described for the production of iron directly from the ore. Here the action of the air from the blast (by that time in general use) would, if the iron were handled properly during melting, result in the oxidation of the silicon and the greater portion of the manganese and carbon, giving a ductile and workable product. The first reference to the process in written records appeared about 1620, but by that time the process had reached a stage of considerable development. Previous to that date, the

FIG. 11-4. General arrangement of a Walloon hearth used for purifying pig iron to make wrought iron.

Walloons of Flanders had gone to Sweden, where they had introduced the process, since known as the Walloon process. In this process a rather deep hearth with one or two tuyeres was used (Figure 11—4). With the hearth filled with charcoal and heated to a high temperature, the pig iron, in the form of long pigs, was fed into the fire so that the lower end of the pig would be gradually melted, and the molten metal would trickle to the bottom directly in front of the blast. The metal, desiliconized and decarburized by the oxygen in the air blast, would collect as a pasty mass upon the bottom, being worked vigorously as it collected. The ball of pasty metal was then separated into lumps that were raised above tuyere level and remelted. The new ball formed on the bottom was then removed from the hearth and hammered into a bloom. The second melting freed the metal from much of its entrapped slag. The pig used in Sweden, since it was reduced from the famous Dannemora ore in charcoal furnaces, was exceptionally low in silicon, sulphur and phosphorus, hence was especially adapted to this process.

South Wales Process—Few districts outside of Dannemora are favored with ore so free from phosphorus, or were able to continue using charcoal for fuel for such a period of many years. The use of coke in the blast furnace leaves no alternative but the production of high-silicon iron, if the sulphur content is to be kept suitably within limits. At the lower temperatures necessary to produce low-silicon iron, more of the sulphur content of the coke will be picked up by the iron. Such iron, high in sulphur and silicon, could not be purified in a single operation, as in the Walloon process, where the purification was carried on in the combustion chamber with the metal and slag in contact with the fuel. It was found, however, that this iron could be purified and converted into wrought iron very readily in two stages. The South Wales process (sometimes confused with the Lancashire process) was a typical two-stage process. For the first stage, a small, rectangular, water-cooled hearth, surmounted by a stack and provided with a number of tuyeres, was used. In some cases, this hearth was a separate structure; in other cases this hearth for melting the pig iron formed part of a two-hearth furnace in which the melting hearth was slightly above the second hearth where final refining took place. When a separate melting hearth was employed, coke was used as fuel to melt the pig iron; for refining the melted iron, the second hearth was fired with charcoal. When the two hearths were incorporated into one furnace structure, charcoal was used as fuel in both. Sometimes two charcoal hearths were served by one melting hearth that tapped directly into them. The hearths were known by various names. The melting hearth, when separate, was called the **refinery**, or **refinery fire**, if the metal tapped was allowed to partially or completely solidify before being transferred to the second hearth. If the metal was allowed to flow directly from the refinery into the second hearth or hearths, as in the two-hearth furnace, the melting hearth was known as the **melting finery** or **running-out fire**. In both cases, the second hearth was known as the **finery**, **charcoal finery** or, more often, **knobbling fire**.

With a good fire burning upon the melting hearth, alternate charges of coke and pig iron were made upon it. As the metal melted, it would collect upon the bottom of the melting hearth where the blast from the tuyeres impinged upon it, oxidizing the silicon and some of the phosphorus along with a part of the iron. Assuming that the melting hearth in this case was a separate unit, when a sufficient quantity of partially purified and partially solidified metal had collected, it was transferred to the

second hearth from the melting hearth, being piled in front of the tuyere and completely remelted while exposed to the blast. During the remelting, the metal was worked constantly and repeatedly raised slightly off the bottom, which treatment promoted the oxidation of the carbon. As the carbon was being removed, the metal gradually assumed a pasty condition, when it was worked into a ball, taken from the furnace, and hammered.

Lancashire Process—The Lancashire process differed essentially from the South Wales process, to which its name was sometimes loosely given, in that the pig iron was both melted and refined in a single hearth using charcoal as fuel. With some of the slag left from the previous operation to cover the bottom, the hearth was piled with charcoal up to above the tuyeres. The pig iron in lumps was placed on top of the charcoal pile, covered with more charcoal, and the blast turned on. The pig iron melted in drops which became partially decarburized in passing through the tuyere area and collected on the bottom. When all of the pig was melted, it was worked with bars to mix it with the slag and become thoroughly purified. As purification proceeded the metal became stiff and pasty, and when purification was completed the pasty mass was raised above the tuyeres and melted down again to free it from the intermingled slag. The pasty lump resulting from the remelting process was then taken from the furnace and hammered into a bloom.

These three are only a few of the many types of charcoal-hearth indirect processes developed for purification of pig iron to produce wrought iron.

Hand Puddling Processes—About 1613, Rovenson invented the reverberatory furnace, which he described as a bloomery, finery or chaffery "in which the material to be melted or wrought may be kept divided from the touch of the fuel," but it was not employed for purifying pig iron until 1766, when the Crane brothers received a British patent on a process which later came to be known as **puddling**. With careful manipulation of a reverberatory furnace, they were able to convert "white iron," or pig iron from which most of the silicon and phosphorus had been removed in a refinery, as described under the "South Wales Process," into a good malleable form of iron by the use of raw coal alone for fuel. In 1784, Henry Cort hollowed out the bottom of the furnace so as to contain the metal in the molten state, then by agitating this "puddle" or bath of metal with an iron bar or paddle he was able to convert white or partially-refined pig iron into a malleable form (wrought iron), the carbon being burned out by the oxidizing gases of the furnace atmosphere.

As the furnace bottom was made up of sand, it was rapidly fluxed away by the iron oxide formed. Besides, the process consumed much time and was wasteful of iron, the yield being less than 70 per cent of the metal charged. These objectionable features were largely overcome by Joseph Hall, who, in 1830, substituted old bottom material for the sand, thus introducing the iron oxide bottom, which adapted the process to any grade of iron, shortened the time of the heats, and increased the yield to about 90 per cent. On account of the boiling action of the bath caused by the rapid oxidation of the carbon by the oxides on the bottom, Hall's process came to be known as the **pig boiling process**. Later, this process became the leading method for the production of wrought iron.

The original method was designated as **dry puddling** because of the small quantity of slag formed, the slag-forming impurities having been removed in the refinery (see "South Wales Process," above). Hall, or his asso-

ciates, also introduced the use of air-cooled iron plates for supporting the bottom and sides, which materially increased the life of the furnace. During the next 30 years, few changes were made in the process, for the new process was so far superior to previous ones that there was left little incentive for improvement. This attitude was changed, however, with the introduction of the pneumatic, or Bessemer, process in 1856. Then, in order to overcome competition of the Bessemer steel, and incidentally lessen the labor of puddling, which, like all its predecessors, was very arduous, hundreds of attempts were made to improve and cheapen the process (see Section 8, "Mechanical Puddling"). Few of these attempts were successful, and even the most promising

of the successful ones, for various reasons, failed of universal adoption.

Between the years 1920 and 1930, however, hand puddling was almost entirely abandoned to be supplanted by the Ely mechanical puddler and the Aston process, the former duplicating conditions of hand puddling as closely as possible and the latter employing radically different principles and methods to obtain a similar but more uniform product. These three methods are briefly described in the following sections not only because they will help to define wrought iron and illustrate different methods of producing it, but also because they supply some fundamental knowledge as an introduction to the study of steelmaking processes.

SECTION 4

CONSTRUCTION OF THE HAND PUDDLING FURNACE

Although various modifications were introduced in the construction of puddling furnaces, affecting both size and design, the tendency was to adhere to the smaller and simpler types, such as the one shown in Figure 11-5. This type was known as a single furnace, had a

FIG. 11-5. Diagrammatic sections and elevation (center) of a typical hand puddling furnace of the simple design known as a single furnace.

capacity rating of 500 pounds per heat, and was coal-fired. The furnace was made up of three parts: the grate, or fireplace, located at one end of the furnace; the neck, or flue, at the opposite end, leading to the stack; and the hearth, or puddling basin, centrally located between the grate and the neck. The furnace was constructed entirely of brick, but was encased on the sides by a shell of iron plates held in place by tie rods. As the furnace was of the reverberatory type, all these parts were covered by an arched roof which sloped

from the fireplace to the uptake flue at an angle of 8 to 10 degrees. The roof over the fireplace was built of firebrick, but usually silica brick were used over the hearth and neck. The fireplace, which measured about $3\frac{1}{2}$ feet in length, $2\frac{3}{4}$ feet in width, and $3\frac{1}{4}$ feet in height at the rear, was enclosed on each side by 12-inch firebrick walls and at the rear by a 9-inch wall of the same material. To support the fire bed the space over the ash pit was bridged with iron bars. About 16 inches above the bars a 10-inch square hole in the firebox on the front side of the furnace was provided for firing. The neck, at the other end of the furnace, was an inclined firebrick flue, frequently lined with a course of best-quality silica brick. The neck terminated in a short uptake, or vertical flue, that led to the stack, which was independently supported upon a mantle. At the base of the uptake, directly opposite the neck, was an opening or door, called the floss hole, which was provided primarily for the removal of the cinder that was carried, or overflowed, from the puddling basin.

The hearth, or puddling basin, was the most vital part of the furnace. Externally, the bottom of this basin consisted of three iron plates, 1 inch thick, which were supported upon four heavy bearer bars laid transversely across the space between the side walls of the furnace. This construction provided all the benefits of air cooling. A low brick wall, laid across the furnace and known as the bridge, separated the hearth from the fireplace and also served as a backing for one end of the basin. At the opposite end of the hearth, a somewhat lighter and lower wall, known as the breast wall or altar, separated the basin from the neck. Imbedded in each of these walls next to the lining, was a hollow iron casting, called a chill, through which air or water was circulated to keep these parts cool. The other two sides of the basin were supported by the walls of the furnace itself, and were similarly air-cooled. The back wall was built up solid to the roof, but the front wall contained the arched opening to the hearth. The sides of this opening were made of specially formed silica brick, known as the jambs, while its bottom was made of a heavy iron plate called the fore plate. This opening was closed by a brick-lined sliding door, in the bottom of which was a small U-shaped opening, the rabbling hole, through which tools for working the heat could be inserted without raising the door.

Before the newly-built furnace was put into productive operation, a smooth one-piece working bottom or basin was built up in the hearth. The details of this operation were varied considerably with equally good results. In general, the bottom was composed of a

refractory fettling composed mainly of the ferrosiferrous oxide of iron (Fe_3O_4). Certain grades of ore or of heating-furnace cinder were frequently used, but more

often the bottom was made by applying, oxidizing, and fritting in successive layers of fine iron cuttings (such as thread cuttings from a pipe mill) known as swarf.

SECTION 5

OPERATION OF THE HAND PUDDLING FURNACE

With the hearth properly built up or repaired and the furnace in good working order and at a proper temperature, about 500 pounds of pig iron were charged by hand through the door. Following this operation, occupying 2 to 3 minutes, the purification of the pig iron and the process of puddling advanced by stages, known as melting, clearing, boiling, balling and drawing. To achieve quick melting, the door and other openings were closed, the furnace was fired vigorously, and the pigs turned once or twice by the puddler or his helper. In this way the charge was usually melted within 20 to 25 minutes after charging. The molten metal, covered with a thin layer of slag, was then stirred or rabbled by the puddler to hasten the oxidation of the silicon, the manganese, and a part of the phosphorus, an operation known as clearing and requiring 8 to 10 minutes. As soon as the metal had cleared, as revealed by a change in its appearance, the puddler endeavored to bring on the boil by raising the temperature of the furnace, charging some dry roll scale (iron-oxide scale detached from bars in rolling), and stirring the bath vigorously. After some 8 to 10 minutes of strenuous effort, the oxidation of the silicon and manganese was brought to a point where the carbon could also be oxidized.

As the product of this reaction was the gas, CO, and since the slag was somewhat viscous, the action caused the latter to foam or boil and rise in the furnace. At this point the slag was permitted to flow from the furnace freely unless it was desired to hold the phosphorus high in the iron, when a little coal was added from time

to time and as much of the slag as possible was held in the furnace. As the elimination of carbon became more rapid, the gas would escape in larger bubbles and burst into flame at the surface of the slag to form small flames called puddler's candles. With the disappearance of the candles, the puddler increased the stirring of the bath during the lowering of the heat until the metal in terms of the puddler, would come to nature. In this phenomenon, most characteristic of puddling, the metal appeared in small globules, like butter in churned milk, each globule representing a portion of the iron that had become decarburized. As this reaction neared completion, the bath became pasty and very hard to work. This change occurred because the high-carbon pig iron, which was molten at that temperature, was converted to low-carbon iron, which is solid (though pasty) at the same temperature. The change progressed rapidly, lasting only 6 to 8 minutes, so that in some 30 to 35 minutes after clearing the metal was ready for balling.

The globules agglomerated by the rabbling tended to collect in masses on the bottom, which had to be raised constantly and exposed to the heat to prevent them from freezing to the bottom. So the temperature of the furnace was raised as high as possible, and the metal was worked into a mass which was next separated into three parts or balls of about 150 pounds each, a size convenient for handling with tongs. This operation required about 15 minutes. Each ball in turn was then grasped by the tongs supported from the trolley (Figure 11-6) and drawn through the door. After the last ball was re-

FIG. 11-6. Puddler removing a ball from a puddling furnace for transfer to the squeezer. This photograph, taken in 1949, shows one of the last puddling furnaces still in operation in the United States. (Courtesy, Lockhart Iron & Steel Company.)

moved, the furnace was permitted to cool to some extent, and the bridge and breast were covered with a special ore mix. Any necessary patching of the bottom

was done, and another charge of metal was placed on the hearth for the next heat. These operations required about 2½ hours from heat to heat.

SECTION 6

ROLLING OF HAND-PUDDLED WROUGHT IRON

Shingling or Squeezing the Ball—At one time the balls were worked into the form of a rough bloom with a hammer, an operation called *shingling*. Later, hammering was superseded by the use of a device known as a *squeezer*, of which there were different types. One, known as the Burden squeezer, was most used (Figure 11-7). It was of the rotary type and consisted essentially

FIG. 11-7. (Above) Schematic representation of the path of a puddle ball passing through a Burden squeezer to reduce it to a crude bloom for subsequent rolling. (Below) Elevation of the Burden squeezer.

of a toothed cylinder mounted upon a vertical shaft so as to revolve within a section of a somewhat larger stationary cylinder set eccentrically to the revolving cylinder. Since the larger cylinder bore teeth or cogs on its inner surface and described only about three-fourths of a circumference, a ball placed in the larger opening between the cylinders was carried around the circumference by the smaller revolving cylinder to be compressed and discharged through the smaller opening in the form of a short round bloom. This action squeezed most of the excess slag out of the ball and compressed it into a form more suitable for rolling. As soon as the ball was delivered by the squeezer, it was grasped with tongs and at once delivered to the first pass of the rolling mill.

Rolling the Squeezed Ball—The muck bar mill for rolling the squeezed ball into muck bar was usually a 16- or 20-inch mill and consisted of a single stand or set of rolls, or of two stands in train; that is, end to end and

coupled together. The first pass was of the open-box type * with large fillets at the corners in order to take the cylinder from the squeezer, while the second pass, generally an edging pass, was of similar design, thus working the metal into the form of a round-cornered square and squeezing out more of the slag at each pass. The remaining passes were all of the closed-box or tongue-and-groove type for rolling the bloom into flats called *muck bars*, with some open-box edging passes for use in producing the narrow widths. The size of the muck bars, of course, was regulated by the product to be made from them and the manner or system used in forming the product. For ordinary bar iron, which was the chief product, the muck bar was usually about ¾ inch thick and 2½ to 8 inches wide. Bars of these sizes required from 5 to 9 passes. On account of the rapid cooling of the bar in the rolls, it was not practicable to attempt to roll sizes smaller than these, as the slag was no longer fluid enough at this stage to be worked out of the bar. As slag was squeezed out of the bar at all passes in the mill, the muck bar had a very rough surface with some torn edges and was otherwise unfit to do service as a finished bar. Having been rolled to the size required, the muck bar was allowed to cool before being subjected to further treatment.

Variables in the Muck Bar—Owing to irregularities in the pig iron used, differences in manipulation by different puddlers, and in different plants, the small quantity of metal refined with each heat, and the fact that the metal solidified before purification was complete, muck bar was an exceedingly variable product. Since the retention of the characteristics of wrought iron did not permit melting, this variation had to be overcome through heat and mechanical treatments. To effect the necessary refinement, two methods were used, known as busheling and piling, followed by rolling.

Busheling—Obviously, the surest way to obtain a thorough mixing of the iron, was to shear the muck bars into small pieces—the smaller the better. These small pieces from the different muck bars were allowed to collect in a pile, or piles, from which portions weighing 180 to 600 pounds were removed with a scoop or fork and charged into a reheating furnace, called a *balling furnace*, where they were heated "white hot," or to a self-welding temperature. With a paddle, these pieces were then collected into a ball, similar to a puddle ball, which was squeezed or shingled, then rolled or hammered into a bloom, which was then reheated and worked into the form desired. This process, known as *busheling*, was used for working up muck bar only when iron of the highest quality was desired. The process was also used in working up small scrap. In this case there was no necessity for shearing, and the cost of the scrap was usually considerably less than the cost of muck bar, but unless the scrap was very carefully selected it was liable to contain much steel, in which case the iron produced was considered to be of inferior grade.

Piling—The more common practice, therefore, was to

* See Part 1 of Chapter 23 on "Rolling Mill Rolls and Their Parts" for descriptions of the roll passes mentioned here.

shear the muck bar into lengths of from 2 to 3 feet, then arrange these pieces in piles of from 5 to 7 or more each and bind the pieces together with wire or bands. The piles were carefully charged into a furnace and heated white hot. The high temperature caused the different bars to weld together, so that they could then be removed and rolled into bars. The first 2 or 3 passes squeezed out more and more of the liquid slag, but in the last passes the bar had cooled to a point where the slag was merely plastic and would not flow. Thus, a fairly smooth and uniform bar was produced, which would be sold as **merchant bar**, **single-rolled iron**, **single-refined iron**, or **No. 2 iron**. In order to attain the highest degree of uniformity, particularly with respect to distribution of slag fiber, the once-piled or so-called single-refined bars were in turn cut up into short lengths and repiled and rerolled.

Double Refining—To further improve uniformity, then, merchant bar was cut up into short lengths, fagoted, reheated, and rerolled to produce the products known as **double-rolled iron**, **double-refined iron**, **best bar**, or **No. 3 bar**. The manner or fagoting (binding together into a bundle) or piling these bars varied in numerous ways, and depended only in part upon the use to which the iron was to be applied. Therefore, each manufacturer generally had his own methods of fagoting, which imparted to his iron an individuality detected by etching. Some of the more common methods of fagoting are illustrated by the accompanying sketches (Figure 11—8). When these fagots were heated and rolled into bars, more slag was expelled, the bar was made more uniform in composition, and the fibers were much elongated and reduced in size. As a result, the bars showed an improvement in mechanical properties, including both strength and ductility. There was a limit, in addition to the factor of cost, however, to the number of times the iron could be worked to advantage. After five or six workings its physical properties began to be lowered, and the bars decreased in strength and were less ductile. The cause, or causes, of this change was

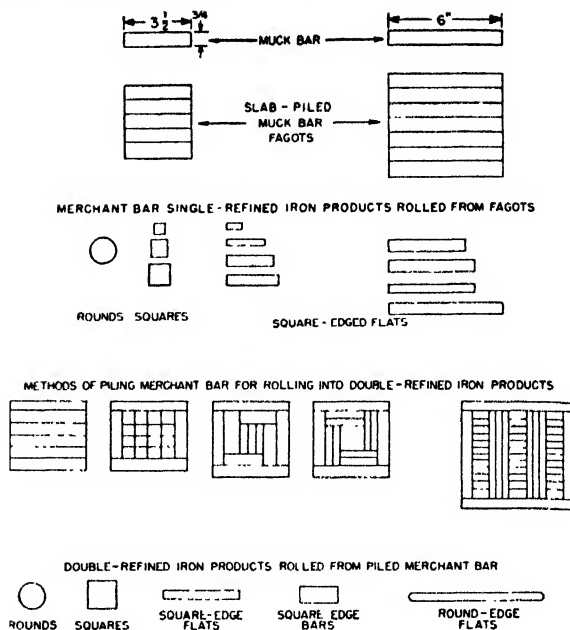

Fig. 11—8. Some of the more common methods of fagoting or binding together piles of single-refined wrought iron bars prior to heating for re-rolling to produce double-refined wrought iron bars.

questionable; probably, it was due to the elimination of much of the silicate slag or possibly too much reheating and rerolling caused the ferrous silicate fibers to become oxidized to the ferric condition, thus destroying some of the characteristics of wrought iron. Wrought iron in this condition was often referred to as **dry iron**.

SECTION 7

REACTIONS AND PROCESS LOSSES IN HAND PUDDLING

The changes in composition of the pig iron during puddling involved the elimination, or oxidation, of silicon, manganese, phosphorus, and carbon about in the order mentioned. In these reactions, the oxidizing agents were FeO and Fe_3O_4 . That Fe_2O_3 played little, if any, part in the reactions was evident from the fact that Fe_2O_3 decomposed at temperatures above 1010°F (1100°C) to form Fe_3O_4 . Also, it had been found that if hematite ore (Fe_2O_3) was used as the oxidizing medium, the boil came on very slowly; but if roll scale (Fe_3O_4 or $\text{FeO}\cdot\text{Fe}_2\text{O}_3$) were used, the reactions proceeded with much greater speed. Nearly all of the silicon and manganese and a part of the phosphorus were oxidized before the boil began, and at some period after melting and after the elimination of some of the silicon, the oxidation of all four elements, including carbon, might have proceeded simultaneously.

A study of the probable reactions that occurred in puddling indicates that a gain in weight of the puddled iron over the pig iron used could be expected, because iron was formed by reduction from the slag in the elimination of practically all impurities. By careful manipulation, furnaces could be operated to show a slight gain or a very slight loss. Nevertheless, in ordinary

working, there was a loss of from 3 to 6 per cent, which was sometimes a little more, at other times a little less, than the total of the impurities present. If the heat was properly handled, the loss was largely due to oxidation of iron after solidification had begun in the after-part of the boil and during the balling stage. If the heat was not skillfully handled, a variable part of the loss may have been due to the escape of the metallic granules with the "boilings" before the "heat was lowered." In reheating and rolling the muck bar, there was a variable loss of from 10 to 20 per cent for each time the iron was worked depending upon the number of times it was worked, the manner of the working, and other factors incidental to the operations of heating and rolling. In general, these losses were due to surface oxidation of the metal in heating and rolling, expulsion of the slag, and cropping. Slag expulsion was the smallest item of loss, except in the case of muck bar, and depended mainly upon the number of times the iron was worked, but was also affected by the temperature at which the iron was worked, and the nature of the incorporated slag itself. The loss was a little greater on iron with a high phosphorus content than on iron low in phosphorus.

SECTION 8

MECHANICAL PUDDLING

The never-ending competition in the iron and steel industry has been a constant spur to improve methods or lower costs of production. Just as the puddling process virtually eliminated the more primitive direct-reduction methods for the production of iron, so the Bessemer and open-hearth processes for the production of steel threatened the life of the wrought-iron industry. Even before the invention of these steelmaking processes, much attention was given to improving the puddling process, because the process was costly and the labor arduous, and the furnace was wasteful of heat. With a reverberatory puddling furnace of the type described earlier, from 2000 to 2400 pounds of coal were required to produce one ton of muck bar. This consumption of fuel was reduced somewhat by the use of double furnaces with enlarged hearths, but, since the application of regenerative and recuperative furnaces appears to have been impracticable, efforts along this line failed to achieve much in the way of lowering costs. The installation of waste-heat boilers in the stacks effected marked economies, and their use became general. To overcome the high labor cost, many attempts were made to carry out the puddling operations mechanically. Such was the situation up to about 1880 when the Danks puddling furnace appeared. From this time up to 1925, wrought iron lost ground to steel in spite of several efforts to revive it. In the meantime, however, it came to be recognized as a product with characteristic properties unlike those of steel, and in 1925 attempts to revive the industry were noted. These endeavors advanced along two lines, the one mechanical and the other metallurgical, the former aiming to duplicate the process of hand-puddling as closely as possible and the latter aiming to produce a material having all the characteristics of wrought iron through the use of the same metallurgical principles but applied in a manner entirely different from that of hand puddling. These two lines of effort are described under the headings of mechanical puddling and the Aston process, the latter representing a successful and most revolutionary method of producing wrought iron by A. M. Byers Company.

Principles of Mechanical Puddling—At first these mechanical puddlers took the form of stirring or rabbling appliances that could be attached to the top of the ordinary furnace. Because of the great variety of motions necessary in the different operations of charging, raising and stirring the heat, balling the iron, and drawing the balls, none of these were successful. The more successful attempts at mechanical puddling have involved a complete change in the design of the furnace, and some changes also in the process. These attempts have been too numerous to warrant description here. The furnaces themselves may be classified as follows:

1. The rectangular furnace that oscillated about a horizontal axis of rotation.
2. The circular flat-bottom furnace that revolved about an axis slightly inclined to the vertical.
3. The circular furnace with flat or troughlike bottom that oscillated about a horizontal axis of rotation.
4. The cylindrical furnace that rotated about a horizontal axis coincident with the center.
5. The cylindrical furnace that oscillated about a horizontal axis coincident with the center, or both oscillated and rotated about such an axis.

Furnaces built on any of these plans were made to puddle iron successfully, but those of the fourth and fifth types were most successful, partly on account of the facilities they afford for controlling the agitation of the metal, and partly because of the simplicity of their construction. The **Danks furnace**, somewhat widely used in this country from 1868 to 1885, was of the fourth type, while the **Roe furnace**, built and successfully operated in 1905, is of the third type. **H. D. Hibbard's furnace**, first operated on a commercial scale in 1921, was somewhat similar to the Danks furnace. The **Ely furnace**, patented by W. C. Ely, was first designed for busheling scrap but was later (about 1920) applied to the puddling of iron. It represents the fifth type, and, along with the Roe furnace, survived until recent years as two successful mechanical methods for making wrought iron.

SECTION 9

THE ASTON PROCESS *

From the descriptions given in the preceding sections, it is apparent that the basis of wrought-iron manufacture consists in refining the base metal to a close approach to pure iron, and incorporating therein an iron-silicate slag of desirable chemical composition in proper amount and distribution. Obviously, as has been brought out previously, several correlated steps are involved, quite distinct in nature and capable of separation, but carried out in the usual methods for hand or mechanical puddling as one interconnected operation. Departing radically from these former methods is the Aston process developed and put into large scale operation by the

A. M. Byers Company of Pittsburgh. In this process, metal refining, slag melting, and processing to form the slag-impregnated sponge ball are carried out as separate stages, each stage in a separate furnace or kind of equipment. The last stage is the crux of the process, and is based upon a positive and effective physico-chemical influence; namely, the change in gas solubility from a very high amount in molten iron to an amount practically negligible on solidification. This stage of the Aston process is carried out by pouring the refined metal in a continuous stream into a large volume of molten slag. The slag acts as a heat absorbing agent which effects solidification of the metal, with accompanying liberation of its dissolved gases, at a steady rate and with a force sufficient to disintegrate the plastic metal into a spongy mass, conforming in all particulars to the characteristics of high-quality wrought iron.

* Special acknowledgment is made of the assistance rendered by A. M. Byers Company, in the preparation of this section.

FIG. 11-9. Three cupolas engaged in the continuous melting of Bessemer-grade pig iron to produce molten iron for refining in the converter shown in Figure 11-11. (Courtesy, A. M. Byers Company.)

A large plant, with a daily capacity in excess of 1000 tons, is in operation in the Pittsburgh district. The essential features of the operation are illustrated in the accompanying Figures 11-9 to 11-14.

In the absence of hot metal from a blast furnace, standard Bessemer pig iron is melted in three cupolas operating continuously to produce molten iron for subsequent refining (Figure 11-9).

The iron-silicate processing slag is melted to exacting chemical requirements in special furnaces, which are described later (see also Figure 11-10), and then transferred to the processing cups.

Molten iron from the cupolas is blown to the low metalloid content of "full-blown" Bessemer steel in an acid-lined converter (Figure 11-11), and the highly refined metal is poured at an automatically controlled rate into a cup or thimble holding molten slag (Figure 11-12). After the metal from the converter has been

poured, the surplus slag is poured from the thimble, leaving the white hot sponge ball of wrought iron (Figure 11-13). This sponge iron is first pressed into a bloom of rectangular section (Figure 11-14) and is then rolled into slabs or billets.

Equipment for melting iron-silicate slag for the processing operation (sponge-making), and for incorporating in the matrix of iron, consists of four rotary furnaces. These furnaces, which are fired with oil or powdered coal, have no refractory lining and are operated in such manner that the lining material is composed of the same silicate slag that is being melted. This eliminates all contamination which would occur with customary refractory linings and makes it possible to produce the iron-silicate slag for processing to a very exacting chemical composition.

The key operation is effected by pouring the converter metal in a steady stream into a "processing cup" or

FIG. 11-10. Rotary furnace fired with pulverized or powdered coal for melting iron-silicate processing slags used in the Aston process for making wrought iron. (Courtesy, A. M. Byers Company.)

vessel containing molten slag as illustrated by Figure 11-12. The metal ladle is automatically oscillated and moved forward and backward, insuring uniform distribution of metal into the slag. A sponge ball results as explained heretofore. The general size of bloom in present practice is three to four tons, and the pouring rate is one ton per minute.

FIG. 11-12. Forming the slag-impregnated sponge ball characteristic of the Aston process for making wrought iron by pouring refined blown metal into molten slag. (Courtesy, A. M. Byers Company.)

FIG. 11-13. Decanting surplus slag from the processing cup, leaving the slag-impregnated, white-hot sponge ball of wrought iron. (Courtesy, A. M. Byers Company.)

These processing cups are on cars, so that the decanting of surplus slag and the dumping of the sponge ball (Figures 11-13 and 11-14) can be effected at a station remote from the pouring platform.

Pressing and rolling follow, using the original heat of the ball, to form intermediate products such as billets or slabs conforming to standard mill practice. Furnaces, mills, and auxiliary equipment, as well as man power, follow closely the standards of the modern rolling mill. In view of the large mass of the pressed bloom, most of the product—skelp, plate, etc.—is rolled from reheated solid sections, in marked contrast to older wrought-iron practice of building muck bar piles.

FIG. 11-14. White-hot sponge ball of wrought iron on the table of the machine which squeezes it into a rectangular bloom prior to rolling. (Courtesy, A. M. Byers Company.)

SECTION 10

COMPOSITION, STRUCTURE AND PROPERTIES OF WROUGHT IRON

Chemical Composition of Wrought Iron—Chemical composition has a place in the determination of wrought-iron quality comparable with its importance in the steel industry. One must bear in mind, however, that the customary metalloids may be, in greater or lesser degree, alloyed with the base metal or associated as oxidized constituents with the intermingled slag. The commonly reported composition of wrought iron lists the carbon, silicon, sulphur, phosphorus, and manganese of the composite mass. The ideal analysis should separate the metal from the slag, and reveal the metalloid distribution between the two. On the basis of analyses as commonly made, the following statements apply to wrought iron of high quality: Carbon content is generally 0.02 to 0.08 per cent, the lower percentages being more typically representative. Silicon content is 0.10 to 0.20 per cent, normally almost negligible in alloyed association with the metal, and existing almost entirely as silicates in the slag. Sulphur is always undesirable, and in well-made wrought iron, it should be under 0.03 per cent. A sulphur content of 0.025 per cent or under is quite common in quality wrought iron. Phosphorus is almost invariably higher in wrought iron than in steel. It must be borne in mind that phosphorus is in part dissolved in the base metal, and in part associated with the slag. Good wrought iron may have a phosphorus content of from 0.10 per cent or less to 0.25 per cent or more, according to manufacturer's preference, nature of raw materials, or adaptability to service conditions. The lower order is advisable for materials subjected to shock, high temperature, or requiring higher ductility. Manganese is usually under 0.05 per cent, due to refining conditions and to the fact that there are no after additions. This characteristic of real wrought iron has caused a manganese content of 0.10 per cent or more to be taken as indicative of steel scrap adulteration. Low manganese in wrought iron has usually been an earmark of quality, although there is no logical ground for condemning an otherwise well-made product because of a relatively high manganese content.

Macroscopic Structure of Wrought Iron—In view of the composite nature of wrought iron, its quality is ob-

viously affected by the nature of the association of base metal and slag. Methods of disclosing this internal structure have an importance greater even than the prominent place which the metallurgist assigns to them in the study of steel. Wrought iron exhibits a well-recognized fibrous fracture. The fracture test is a good over-all means for determining the general characteristics of wrought iron, but it should not be relied upon solely.

Macroscopic etching will reveal gross structure, reflecting such features of manufacture as methods of piling, and general slag distribution. Deep etching has a useful place but, like the fracture test, gives only a limited amount of information pertaining to the finer points of quality.

Microscopic Structure of Wrought Iron—Wrought iron consists essentially of a ferrite matrix, through which the slag is uniformly disseminated in the form of several hundred thousand filaments per square inch. Important disclosures of the microscope are:

- Grain Size**—Coarse grain, distortion, or lack of uniformity have a bearing upon quality in relation to mill history and use of product.
- Pearlitic areas** indicate the quantity and nature of distribution of the carbon, generally practically negligible or quite small in amount in real wrought iron.
- Slag—Type and Distribution**—Coarse, pocketed slag is undesirable. Finer textures result from progressive rolling reductions, and promote better mechanical properties, especially ductility.
- Chemical Composition**—The microscope is of no value in detection of alloying elements in solid solution in the base metal; for example, manganese, nickel, silicon, copper, etc.

Two photographs (Figures 11—15 and 11—16) illustrate typical structures and features related to the quality characteristics of wrought iron. These micrographs are of wrought iron produced by the A. M. Byers Company (Aston process), and show a typical longitudinal structure and a typical transverse structure.

FIG. 11—15. Photomicrograph at 100X showing typical structure of wrought iron parallel to the direction of rolling. White areas are the highly refined iron matrix. Dark gray elongated lines are iron-silicate slag filaments. (Courtesy, A. M. Byers Company.)

FIG. 11—16. Photomicrograph at 100X showing typical structure of wrought iron perpendicular to the direction of rolling. White areas are the highly-refined iron matrix. Dark areas are cross-sections of iron-silicate slag filaments. (Courtesy, A. M. Byers Company.)

Mechanical Properties of Wrought Iron—The mechanical properties of wrought iron are essentially those of pure iron, modified only slightly in general practice by metalloid content of the base metal and profoundly by the quantity and distribution of the incorporated slag. Up to certain limits, the ductility is increased by greater work in forge or mill, which causes a finer and more threadlike distribution of the slag. This is reflected in the common practice of the puddle mill of once or twice piling in products designated as "single" or "double-refined" iron. Obviously, a similar result will be achieved by rolling relatively large initial blooms into small final sections.

In comparison with steel or ingot iron, the longitudinal ductility of wrought iron is somewhat lowered, due to slag incorporation, while the transverse strength and ductility are markedly reduced. However, rolling history is an important factor with respect to quantity and direction of reduction.

The values below are representative of tensile properties for various wrought-iron products, compiled from standards of the American Society for Testing Materials. Because of the physical size of the products listed, only the longitudinal properties are reported, except for plate for which both longitudinal and transverse properties are given.

BAR IRON—SINGLE-REFINED

Under 1¼ Sq. In. Section

Tensile strength, lb. per sq. in. 48,000 (minimum)
Yield point, tensile strength factor ... 0.6
Elongation in 8 in., per cent. 25 (minimum)
Reduction of area, per cent. 45 (minimum)

BAR IRON—DOUBLE-REFINED

Under 1¼ Sq. In. Section

Tensile strength, lb. per sq. in. 48,000—52,000
Yield point, tensile strength factor ... 0.6
Elongation in 8 in., per cent. 28 (minimum)
Reduction of area, per cent. 48 (minimum)

The higher ductility accompanying greater work is reflected in the figures for double-refined material. For heavy sections, such as large diameter bars and forgings, strength and ductility requirements are somewhat lowered.

WELDED PIPE

Tensile strength, lb. per sq. in. 40,000 (minimum)
Yield point, lb. per sq. in. 24,000 (minimum)
Elongation in 8 in., per cent. 12 (minimum)

Herein are reflected the effects of high temperatures in welding, and the lessened stretch in testing tubular sections. However, where special precautions are taken in the making of pipe for bending purposes, the ductility figures are bettered in practice by several per cent in the elongation obtained.

PLATE

Under normal rolling practice, plate exhibits the maximum of difference in longitudinal and transverse properties. The A.S.T.M. specifications for usual rolling require plate meeting the following tensile properties:

Tensile strength, lb. per sq. in.
Longitudinal 48,000 (minimum)
Yield point, lb. per sq. in.
Longitudinal 27,000 (minimum)
Elongation in 8 in., per cent:
Longitudinal 14 (minimum)
Transverse ... 2 (minimum)

By proper attention to rolling practice, it is feasible to equalize the properties, so that a specification requirement of a tensile strength of 39,000 lb. per sq. in. (minimum) and an elongation in 8 in. of 8 per cent (minimum) in either direction may be obtained. This feature is of great value in producing plate for flanging or other forming purposes.

Chapter 12

THE MANUFACTURE OF PIG IRON

SECTION 1

HISTORY, PRODUCTION AND KINDS OF PIG AND CAST IRON

No one knows when man first used iron, for that date belongs to prehistoric times. Meteorites probably supplied early man with the first specimens of the metal; knowledge of how to obtain iron from its ores came much later. Archeological research can establish only that iron has been in use through a period of about four thousand years. There is thought to be some evidence of its use by the Egyptians in building the pyramids, about 3000 B.C., but this use is questionable. As to its use by the ancient Hebrews, by the Assyrians about 1400 B.C., and by the Greeks, there is less doubt. The arts of the Greeks, which involved little iron, were followed by those of the Romans, who became somewhat proficient in its metallurgy. The Romans, through their numerous and extensive conquests, the success of which they no doubt owed to the use of metals in making their instruments of war, spread the art of extracting and fashioning iron throughout Europe. Some knowledge

of the metal, however, had preceded them, for Caesar, crossing the English Channel, found it in use among the native Britons. During the Roman occupation of England, the industry grew to one of importance. At that time, and for centuries thereafter, iron was obtained by heating ore and charcoal in a furnace or forge, until there had collected a small body of pasty metal which then was drawn and worked by hammering to make wrought iron. Such methods were described in Chapter 11.

It is also described in Chapter 11 how, around 1350 A.D., the ironmakers of Central Europe developed furnaces that would melt iron and permit of casting; this was iron with a high carbon content—cast iron. This result they accomplished in a new type of furnace, built of masonry, which enclosed a shaft or vertical opening in the form of two truncated cones placed base to base—in a crude way, the lines of the modern blast

THE BLAST FURNACE

THIS IS NOT AN ENGINEERING DRAWING. THE VARIOUS PIECES OF EQUIPMENT ARE NOT DRAWN TO THE SAME SCALE. THE SKETCH IS INTENDED ONLY TO SHOW THE MAJOR EXTERNAL FEATURES OF A BLAST FURNACE AND ITS AUXILIARIES, THE SOURCES OF RAW MATERIALS, AND DISPOSITION OF THE PRODUCTS.

furnace. The lower frustum came to be known as the bosh and the upper frustum as the shaft. In this furnace, ore, flux, and charcoal were charged in at the top of the shaft, while air, under relatively very low pressure, was blown in near the bottom of the bosh. This method was introduced into England about the year 1500 where, in 1619, coke was first used as fuel, to be followed about 200 years later by the introduction of hot blast. In America, an iron works was established in Virginia on the James River, about 1619; this was destroyed in an Indian raid in 1622 and never rebuilt. The Hammersmith (now Saugus), Massachusetts iron works (recently restored) was begun in 1645 and was the first successful iron works in what is now the United States, not being abandoned until 1675.

The American furnaces of a period as recent as one hundred years ago now would be called very crude affairs. Portions of some of them still are standing. They were usually in the form of a truncated cone or pyramid, twenty to thirty feet high, and constructed of stonework which enclosed a shaft, about four feet across at the top and eight feet at the bosh. The hearth was either round or square in cross section. The capacity ranged from one to six tons a day. About the middle of the Nineteenth Century, the size of furnaces began to be increased, and by the year 1880, the output gradually had been raised to nearly 100 tons per day, with a daily coke consumption of nearly 300 tons. With all the basic

principles in use for so long a time, it may seem surprising that progress toward greater efficiency was made so slowly. About 1880, in the vanguard of the great industrial expansion, very rapid advancement began to be made, so that now there are furnaces, the daily pig-iron output of which exceeds 1,600 tons with a fuel consumption of less than 1,500 pounds of coke per ton of iron produced. A diagrammatic sketch of a modern blast furnace and its principal auxiliaries is shown in Figures 12-1 and 12-2.

Attention is called to these facts because it is well to remember, in beginning the study of the modern blast furnace, that the present method for the extraction of iron from its ores represents a very old pyrochemical process which only recently attained its present high state of engineering development.

The Importance of Pig Iron—Pig iron, besides being used directly in the form of castings, is the intermediate form of iron through which all commercial ferrous products, except sponge iron, must pass. Its importance is emphasized by Table 12-I, which summarizes yearly production for the United States during the twenty-five year period from 1930 to 1954, inclusive.

Kinds and Grades of Pig Iron—Pig iron is defined as the direct metallic product, either solid or molten, of a blast furnace smelting iron ore, though it is possible to make a similar material in other ways, for example, by melting steel scrap with an excess of carbon in an

electric furnace. The transfer and use of the pig iron in the liquid state is common for steelmaking; in this form it is referred to as hot metal. When it is desired in small shapes, or pigs, for convenience in handling in the cold, solid form, it generally is cast into traveling molds attached to an endless conveyor forming part of a pig machine or pig-casting machine, and the name pig iron is retained. The qualifying phrase "smelting iron ore" is required in the definition to distinguish the

blast-furnace operation for pig iron from its operation for the other products of the blast furnace, such as ferromanganese, spiegeleisen, silicospiegel, ferrophosphorus, and alloy iron, in which cases manganese ore or iron ore mixed with other ores is charged. "Direct metallic product . . . of the blast furnace" distinguishes pig iron in any form from cast iron, which may be made solely of pig iron, with or without refining treatments, or from mixtures of pig iron with steel, or with other

alloying elements, such as copper, nickel, and chromium. Pig iron is the crudest commercial form of iron, but is made nevertheless in many grades as shown in Table 12—II, along with other products of the blast furnace.

Chief Metallic Products of the Blast Furnace—The chief metallic products of the blast furnace may be classified as follows:

(1) according to raw materials used, as **charcoal pig**, **anthracite pig** (both now practically extinct), **coke pig**, **hematite pig**, **titanium pig**, **chrome-nickel pig**, etc.;

(2) according to the use for which it is intended, as **acid pig** (in the United States, **Bessemer pig**), for the acid Bessemer or acid open-hearth process; **basic pig**, for the basic open-hearth or basic Bessemer (Thomas) process; **forge pig**, or **puddling iron**, for wrought-iron manufacture; **malleable pig** for making malleable cast iron; and **foundry pig** for use in the iron foundry for making castings of various kinds; and

(3) according to chemical composition, as **silicon pig**, **low-phosphorus pig**, **high-phosphorus pig**, **alloy pig**,

spiegel or **spiegeleisen**, **silicospiegel**, **blast-furnace ferrosilicon** and **ferromanganese**.

Formerly, ordinary grades were judged for quality or suitability by the appearance of the fractured surface of broken pigs, the color of which may be white, silvery gray, gray, or mottled, with either small or large crystals in the last two. Although the fracture is a convenience in sorting or selecting iron, grading in the United States is now on the basis of chemical composition, the chief products of the blast furnace according to this classification being represented in Table 12—II. Study of this table shows that blast-furnace products fall into three general types: (1) **conversion pig irons** which are used to make wrought iron and the many varieties of steel, in which processes they lose their identity, being converted into an entirely different product; (2) **pig iron** for castings, the characteristics of which are discussed in detail in Chapter 18; and (3) **ferroalloys**, which contain a high percentage of one or more metallic elements and are used as **addition agents** to regulate the composition of other ferrous metals.

SECTION 2

OUTLINE OF THE BLAST-FURNACE PROCESS

Furnace Input and Output—Essentially, the blast-furnace process consists of charging iron ore, fuel (coke), and flux (limestone and dolomite) into the top of the furnace and blowing heated air (blast) into the bottom. A rough statement of the input of each material per ton of iron produced would be 2.0 tons of ore and iron-bearing materials, 0.9 ton of coke, 0.4 ton of a mixture of limestone and dolomite, and 3.5 tons of air. From these materials, there is produced 1.0 ton of iron, 0.6 ton of slag, 0.1 ton of flue dust, and 5.1 tons of blast-furnace gas. These figures are for present materials which are available to the territory that borders the Great Lakes and which produces about 75 per cent of the pig iron in the United States. As the purity of the materials used varies, the proportions of both the materials charged and the materials produced will vary accordingly.

Functions of the Charged Materials—The function of the ore, as well as the other iron-bearing materials, is to supply the element iron which, in turn, represents about 93½ per cent of the pig iron. The ore is usually in the form of the oxide, either hematite (Fe_2O_3) or magnetite (Fe_3O_4), although there may be small proportions of limonite ($2\text{Fe}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$) or siderite (FeCO_3) present. Hematite represents the largest proportion and usually comes from the Lake Superior region. When chemically pure, hematite contains 70 per cent iron, but present ores contain about 50 per cent iron, the difference being represented by **gangue** which consists mostly of silica and alumina, about 12 per cent moisture, and 6 per cent chemically-combined water.

Other iron-bearing materials are mill-scale, sinter, slag from open-hearth furnaces or Bessemer converters, and scrap. Scale (Fe_3O_4) is a by-product of hot-rolling operations, which drops from the heated piece as it passes through the rolls. Sinter is blast-furnace flue dust (or a mixture therewith of fine ore) which has been agglomerated to form a granular, relatively coarse material. Open-hearth slag is a by-product from the steel-making process containing about 25 per cent iron and an excess of bases over acids, thereby replacing a certain quantity of basic fluxes, but increasing somewhat the total quantity of slag per ton of iron. Basic open-hearth slag also contains sufficient manganese to make

FIG. 12—3. Diagrammatic cross-section of a modern blast furnace, identifying principal structural elements, and indicating flow of materials.

it a valuable source of this element. Its use is limited to the production of irons wherein the phosphorus content is not raised too much thereby; also, it is not charged into blast furnaces producing "blowing iron" for the acid Bessemer process because the manganese it contains would contribute to making a too-fluid slag in that process by raising the manganese content of the iron to an undesirable degree. Converter slag, a by-product of the Bessemer process, does not contain the excess bases or phosphorus found in open-hearth slag. Scrap arises in the casting of the furnace, or it may be iron or steel from external sources and used in the blast furnace to increase production.

The function of the coke is two-fold; first, to supply enough heat to attain the necessary temperature for the metallurgical reducing reactions to take place; and second, to supply the reducing agent for the process of reducing or removing the oxygen from the iron oxide in the ore. Sufficient heat is necessary to reduce and melt practically all the iron, most of the manganese, and a small part of the silicon, and to flux and melt the gangue of the ore and the ash of the coke. The incandescent carbon of the coke is inherently a strong reducing agent, and it is thought, itself, to account for about 20 per cent of the reduction taking place in the blast furnace.

The oxygen of the blast unites almost immediately on entering the furnace with the carbon of the coke to form carbon monoxide, which accounts for the balance (perhaps 80 per cent) of the reduction taking place.

The function of the limestone and dolomite is to form a fluid slag of a composition which will restrict appropriately the other elements (silicon, sulphur, etc.) entering the pig iron. These so-called metalloids in turn also control, within limitations, the mechanical and chemical properties of the pig iron.

With this outline of the process of blast-furnace smelting, it is proper to pass on to the apparatus which makes this process possible.

Parts of a Blast-Furnace Plant—The heart of the ap-

paratus is, of course, the blast-furnace structure itself. The sections of the furnace are (1) the lowest part, known as the hearth, (2) the inverted frustrum of a cone immediately above it known as the bosh, and (3) the part known as the stack or shaft (see Figure 12-3). Means are provided at the bottom for the admission of the blast and removal of iron and slag; at the top, apparatus is provided for the charging of the ore, coke, and flux and for the removal of the gas generated in the process. The gas is led to the dustcatcher for the mechanical separation of the major portion of the dust; thence, through the primary and secondary cleaners it is conducted away for use in hot-blast stoves, in metallurgical heating, the generation of steam under boilers, or to operate blowing engines. The blast air is compressed by turbo blowers, steam engines, or gas engines, and driven to the stoves wherein it is heated regeneratively before its entry into the upper part of the furnace hearth. Bins for the storage and selection of the proper proportions of ore, coke, and flux are provided together with means for conveying these materials to the top of the furnace. Incoming materials arriving in railroad cars are either unloaded directly into the bins or by a car dumper from which they are handled for storage by an ore bridge. Incoming materials in boats are handled either by Hulett unloaders, belt conveyors, or modified ore bridges. The molten iron is carried away from the furnace in iron ladles which deliver it to the steelmaking or foundry departments for use in the molten condition, or to the pig machine where it is cast into small blocks for use in the solid condition. The slag is either disposed of molten in cinder ladles or granulated by a high-pressure water spray, in which condition it is used for fill or in the manufacture of cement. The flue dust, collected from the dustcatcher, the primary and the secondary cleaners, is usually recovered and sintered and then returned to the furnace. Besides these, the necessary utilities are steam, power, water, and railroad service as indicated schematically in the flow diagram reproduced as Figure 12-4.

SECTION 3

CONSTRUCTION OF THE FURNACE PROPER

Foundation—The foundation of a large, modern furnace, typified by Furnaces Nos. 11 and 12 at South Works, has to carry a structure which generally rises over 200 feet above the point of pig iron delivery (center line of the iron notch), has a side reaction from the weight of the skip incline and the downcomer pipes, and carries inside of the furnace a column of material about 90 feet high which will vary in temperature from 2800° F (1515° C) down to 300° F (190° C). Such a furnace foundation carries a load of about 20,000,000 pounds. Under the foundation, H-beam piles are driven to bedrock with the top of the piles about 10 feet below yard level. Upon the piles is placed a reinforced-concrete pad some 11 feet thick and 60 feet in diameter. A ring of reinforced concrete 10 feet high and 12 feet wide, with an internal diameter of about 36 feet, is placed upon the pad. The bases for the furnace columns rest on the top surface of the ring. The column bases are tied together structurally and the columns are welded to the column bases, thereby providing a structure which will not move or slip. The columns and bases are protected against a furnace breakout by a masonry sheath, one brick thick. Inside the circular wall or ring of concrete which supports the column bases, about 2 feet thickness of second-quality firebrick are laid—

the top course being leveled off to provide a suitable base for the lowest course of first-quality brick called bottom block that begins the construction of the actual hearth.

Columns and Base Plates—The column bases are 6-inch thick steel slabs, about 5 feet square. The top of each column is covered by a steel cap which is about 3½ inches thick and somewhat less than 4 feet square. The mantle rests on these caps. The columns are provided at both top and bottom with thick angle plates which are welded to the web of the column and to the caps and bases. Each column consists of a 14-inch H-beam core, to the flanges of which 3-inch thick cover plates are welded. The distance between the bottom of the column base and the top of the column cap is about 36 feet. On a large furnace, such as being described, there would be eight or ten columns.

Mantle—The mantle is a horizontal heavy steel ring resting on the column caps. It supports the furnace shell and the brickwork of the inwall or shaft so that, when necessary, the hearth and bosh brickwork may be removed without disturbing the inwall brickwork. It is built of heavy steel plates which are reinforced circumferentially by circular, heavy, welded-steel bands and by web plates.

FIG. 12-5. Section through the bosh and upper part of the hearth wall of a large blast furnace showing details of connections between the tuyere and bustle pipe, and of the iron notch and cinder notch.

Shell—The shell of a blast furnace is in the form of a truncated cone with steep sides, topped by a flatter truncated cone called the **top cone**. The part below the top cone encloses the shaft of the furnace (Figure 12-3). Formerly, the shell was constructed in "shingle" fashion; that is, the edges of adjacent plates were overlapped and riveted. However, on the furnaces being described, the shell is an all-welded structure, with the edges of adjacent plates matched and butt-welded. This design gives the shell a continuous, relatively smooth surface free from lapped and riveted joints; it also uses less steel, is cheaper to erect, and is stronger than the previous construction. The plates used to construct the top and bottom parts of the shell usually are thicker than those used in the middle section, perhaps $1\frac{1}{2}$ inches compared to 1 inch. The shell is welded at the bottom to the mantle. Openings at selected regular intervals in the shell allow for the insertion of cooling plates into the brickwork with which the shell ultimately is lined. The bottom of the cone at the top of the shell is welded to the main shell structure. The top opening in this cone receives the **lip ring**, a heavy steel casting that may be of one piece or of joined segments. The lip ring is bolted to the top cone, and must be located concentrically; it supports the large bell hopper and the other filling equipment on the top of the furnace. There are regularly-spaced openings in the top cone to which the offtakes, usually four in number, are welded and which conduct the gas formed in the smelting process out of the furnace.

Hearth—It has already been mentioned that second-quality firebrick are laid in the concrete ring on the foundation to form a base for the bottom of the hearths of the furnaces being described. On top of this base, seven rows of first-quality 18 by 9 by $4\frac{1}{2}$ -inch fireclay bottom block were laid on end giving a total thickness of 10 feet, 6 inches. On top of these bottom blocks, two rows of large carbon blocks ($22\frac{1}{2}$ inches thick, 30 inches

wide and up to 15 feet long) were laid, giving a total thickness of carbon of 45 inches. Again, on top of the carbon a single course of fireclay blocks was placed on end. The sides of the crucible or hearth were constructed of two courses of carbon brick, with a total thickness of 33 inches, up to the center line of the cinder notch.

Not all modern furnaces employ carbon refractories in construction of the hearth; those that do not are built entirely of fireclay refractories. Neither do all furnaces using carbon refractories employ exactly the construction just described.

Located about 42 inches above the surface at the bottom of the hearth is the **iron notch** or tapping hole (Figure 12-5) through which the iron accumulated in the smelting process is drawn off at periodic intervals—usually four or five times per day. The slag or cinder, being lighter, floats on top of the molten iron and is drawn off at intervals through the **cinder notch** or **monkey**. The cinder notch assembly consists of three water-cooled, concentric, cast-copper frustrums of cones, the largest, known as the **monkey cooler**, supporting on its inside a smaller frustrum, known as the **intermediate cooler**, which in turn supports the **monkey** itself (Figure 12-5). The central opening in the monkey is closed by a **bott**, which is a tapered water-cooled plug on the end of a steel rod. The bott, on large furnaces, is operated mechanically by a device known as the **cinder-notch stopper**. On the larger furnaces, such as these, two cinder notches usually are installed.

In time, the bottom is eroded to various degrees and is replaced by a large mass of metal known as a **salamander**.

A series of 6-inch thick, cast-iron **staves** surround the hearth sidewalls, extending about 4 feet above and 12 feet below the center line of the iron notch. The tops of the staves are at about the level of the working floor around the furnace; in most modern furnaces, they

are embedded in the brickwork or concrete below floor level. Water-cooling pipes are cast into the staves to reduce the temperature of the hearth sidewalls. A 1½-inch thick steel **hearth-jacket plate** surrounds the staves for approximately their full height to resist the bursting stresses from the inside of the furnace. The staves are modified for the iron notch and cinder notch openings. At the iron notch, it is the practice to place a removable stove, about one-half the height of the normal stove, as a means for a quick repair should a breakout occur at this location.

Above the tops of the cooling staves, the brickwork of the hearth wall is enclosed on the outside by a **tuyere jacket or breast plate**, made of welded 1½-inch thick steel plate. Reinforced openings are provided in this jacket for insertion of the **tuyere coolers**, **cinder notch** and **cooling plates**, all of which fit their respective openings closely. Some of these details may be observed in Figure 12-5, which shows a section of the bosh and the upper part of the hearth. The cooling plates are flat, water-cooled copper castings which extend into the brickwork of the hearth sidewalls. Usually, there are one or two rows below the tuyere-cooler level and three rows between the tuyere-cooler openings. Another method of construction is to use steel castings for the tuyere jacket instead of the welded-steel plate construction. Recently, on furnaces with carbon-hearth linings, water-cooled iron castings in which pipes have been cast (similar to a hearth-cooling stove) have been used. In this latter case, a heavy, welded, steel-plate jacket surrounds the castings to resist the stresses exerted by the outward pressure of the furnace contents against the walls of the hearth.

The heated blast enters the furnace through nozzle-like water-cooled copper castings known as **tuyeres**, usually about twenty in number in a large furnace, spaced around the hearth about a foot below its top (Figure 12-5). The tuyere cooler supports the tuyere in the same manner as the cinder-notch cooler supports the intermediate cooler. For different furnaces in the same plant, the length and diameter of the tuyeres may be different but in all cases they are designed to fit inside the same tuyere-cooler casting. A horizontal cast-iron pipe called the **blowpipe**, about 5 feet long and with one end fitting closely against the tuyere, carries hot blast from the tuyere stock to the tuyere, thence into the furnace. The blowpipe may be slightly larger in diameter at one end than at the other and both ends are turned to fit into slight sockets in the tuyere and the stock. It is held in place with the smaller end fitting into the tuyere by pressure from the tuyere stock which, in turn, is held tightly against the other end of the blowpipe by a heavy spring and rod, called the **bridle**, which is attached to the jacket plate and allows limited motion due to expansion and contraction of the stock and blowpipe with changes in blast temperature. The tuyere stock curves upward on leaving the blowpipe to fasten to the **gooseneck** and is lined with firebrick as a protection against the heat of the blast. In the outer part of the curve in the tuyere stock and on the center line of the blowpipe and tuyere is a small opening closed by the **tuyere cap** or **wicket** through which a small rod may be inserted to clean out the tuyere without removing the blowpipe. The tuyere cap must be of such form that it may be opened readily at any time and still be practically gas-tight. This is accomplished by a tapered plate inserted in guides, in which a small glass-covered opening called the **peep hole** or **eyesight** is placed to permit the inspection of that portion of the interior of the furnace directly in front of the tuyeres. The upper part of the stock is con-

nected by a swivel joint to the refractory-lined nozzle of the gooseneck to which it is clamped by lugs and keys that fit into seats of hanging bars. Each gooseneck in turn is connected by flanges and bolts to a neck extending radially from the inside diameter of the **bustle pipe**. The bustle pipe is a large, circular, refractory-lined and insulated pipe which encircles the furnace at about mantle level and equally distributes the heated blast from the hot blast main to each tuyere connection.

Bosh—Although previously mentioned, the bosh may be described more specifically as that portion of a furnace formed by an inverted frustrum of a cone starting at the top of the vertical sidewalls of the hearth and extending upward to the level of maximum furnace diameter at the mantle. A standard bosh is constructed in the following manner: Starting at the top of the hearth, the brickwork, 27 inches in thickness, is stepped outward, externally, nearly six inches for each twelve inches of vertical rise. Each step-out is supported on the outside by a heavy steel band called a **bosh band**. Extending through the walls of the bosh, fitting closely into cast-iron "boxes" placed in the brick spaces between bosh bands, are cooling plates called the **bosh plates**, in horizontal rows from 18 inches to two feet apart, measured vertically. The plates in each row are several inches apart, and the plates in the different rows are staggered vertically, "breaking joints" like brickwork. This construction adds to the cooling efficiency of the plates. At some plants, it is the custom to place the plates directly in the brickwork, eliminating the cast-iron box entirely. As a safety precaution, a means is usually supplied to prevent the plates from being forced out of the furnace. There are several different makes of bosh plates, but the more common ones are somewhat wedge-shaped, with a flat bottom and oval top, and about four inches thick at the point of their greatest thickness. They are hollow and have inserted in them, usually at opposite corners, two pipes through which water flows continuously; the water enters through one pipe and leaves by way of the other. These plates are necessary to cool and thus protect the brickwork for, being just above the tuyeres, the bricks here are exposed to the highest temperatures in the furnace. In American practice, the bosh has been built of first-quality fire-clay brick, but consideration is now being given to extending the carbon lining of the hearth up to the top of the bosh, which practice is used extensively in Europe.

Regardless of the size of the hearth, the modern furnace has a bosh 9 to 12 feet in height and a **bosh angle** between 80 and 85 degrees (Figure 12-5). In the older furnaces, when a large part of the ore consisted of lumps, the usual bosh angle was about 10 degrees less than at present; but it was found with the use of the finer ores, such as Mesabi, that better results were obtained with a steeper bosh. Also, the height of the older boshes ranged between 15 and 20 feet.

Inwall—The shaft comprises all that part of the furnace which is located above the bosh. The wall of this shaft is usually, in an imaginary way, divided into three almost equal parts, called the **upper**, **middle**, and **lower inwalls**. Up to this point, the construction for all furnaces is fairly uniform in general features, but as to the inwalls, three types are employed, namely, the thick, the intermediate, and the thin wall. The construction necessarily differs among these three types, and each is described separately.

Thick-Wall Type—The inwalls of this type, of which there are many in the United States, have a maximum thickness of five feet, and are enclosed in a heavy riveted or welded steel shell about one inch thick. A space is left between the brickwork and the shell, in

which space is tamped a packing of compressible material to allow for the expansion and contraction of the inwalls. Thick-walled furnaces usually are not water-cooled extensively above the bosh. In case their walls are cooled, this is done by inserted cooling plates.

Intermediate, or Semithin, Wall Type—In the intermediate type, the walls are about three feet thick and, to protect the brick as much as possible, cooling plates (similar to bosh plates) are inserted in the lower inwall. They may extend for a distance of from twenty to forty feet above the bosh. The inwalls are surrounded by a steel shell as in the thicker type, the only difference being in the necessary openings for the coolers. Many American furnaces have linings of this type.

Thin-Wall Type—In this type, the inwalls are from 9 to 18 inches thick, the top is always supported by structural work, and the shell must be cooled throughout its entire length. This cooling may be done in three ways. One method consists in spraying the steel shell with water, conducted through suitably arranged pipes and enclosed by a light splash jacket which conforms to the size and shape of the stack. In the second method, the shell is encircled by a series of deep and narrow horizontal troughs through which water is kept flowing from the top to the bottom of the furnace, overflowing from each trough to the next succeeding lower one. Each of three or four of these troughs drains separately to a common point where the temperature of the water can be noted. In the third type, the entire outer surface of the stack is kept covered with water by a spiral trough which, slightly separated from it, encircles the stack from top to bottom. This trough is kept full of water by a series of feed lines that enter it at various points in the spiral. Few furnaces of this type have been built in the United States, and these gradually are being dismantled.

Relationship of Furnace Dimensions—The relationship of the furnace dimensions, one with another, is most important. Practically all of these relationships are the result of "cut and try" methods, for they do not lend themselves to theoretical calculation. As an example of good furnace design, South Works Furnaces Nos. 11 and 12 have been selected, whose principal dimensions are as follows (see also Figure 12-6):

Diameter of hearth—28 ft.
Diameter of bosh—31 ft.
Diameter of stockline—21 ft. 6 in.
Diameter of big bell—16 ft. 6 in.
Bosh angle— $81^{\circ} 40' 27''$
Inwall batter—1.00 in. per 12 in.
Hearth area—616 sq. ft.
Working volume—47,550 cu. ft.
Number tuyeres—20
Centerline iron notch to top hearth—9 ft. 3 in.
Centerline iron notch to centerline cinder notch—4 ft. 8 in.
Centerline cinder notch to centerline tuyeres—3 ft. 8 in.
Centerline tuyeres to bottom bosh—11 in.
Height of bosh—10 ft. 3 in.
Height straight section lower inwall—9 ft.
Height sloping section inwall—57 ft.
Top sloping section to top of hopper—22 ft. 9 in.

In many quarters, the rated daily production of a furnace is the hearth area in square feet multiplied by a factor from 2.0 to 2.6 which varies primarily with the materials used. The rated daily production of the above furnaces is $616 \times 2.45 = 1,500$ net tons per day. The theory has been advanced that the daily production is a function of the coke burned per day, which in turn is determined by the area in square feet of a ring six feet wide in front of the tuyeres, multiplied by 6,300.

There are two methods for calculating the proper number of tuyeres for a given hearth diameter: the first being to divide the hearth area in square feet by 30; and the second being to divide the inside circumference of the hearth in feet by 4.0 to 4.5.

The working volume of a furnace may be defined as the volume of that part of the furnace through which the gases produced at the tuyeres pass in contact with the materials in the charge. In other words, this volume may be considered as the volume between the centerline of the tuyeres and the stockline. The stockline in this case is assumed to be a horizontal plane located six feet below the big bell in its closed position. The ratio of the working volume to the hearth area should range between 75 and 80, and in this particular case is $47,550 \div 616 = 75.2$. For furnaces producing ferromanganese, this

Fig. 12-6. Lines of typical modern American blast furnaces designed and built during the period 1929-1947.

ratio is even higher than the 80 figure indicated above, being about 90.

An inwall batter of 0.9 to 1.1 inch per foot is desirable which, with the ratio of working volume to hearth area, defines fairly well the stockline diameter. It has been stated that the stockline area should equal the area of the 6-foot horizontal ring in front of the tuyeres mentioned earlier.

The big-bell diameter should be from 4 to 5 feet less than the stockline diameter for smaller furnaces and about 5 to 5.5 feet less for larger furnaces.

The time that elapses from the time the materials are charged at the top until they reach the tuyeres is important because if just sufficient time is available, they will be thoroughly preheated and reduced to the optimum extent by the ascending gases. A derived figure, the theoretical speed at which they descend in the furnace, is also important. The materials next to the wall are in the furnace a shorter time than those in the center since their rate of descent is faster. An average or theoretical figure gives a good check on proper relationship of furnace lines. An example of these theoretical figures is shown below:

	Per Net Ton Iron		Lbs. Per
	Lbs.	Cu. Ft.	Cu. Ft.
Group 3 Ore.....	2748	22.4	122.7
Group 7 Ore.....	923	7.4	125.0
Total Ore.....	3671	29.8	123.3
Open-Hearth Slag.....	395	2.6	150.0
Flux and Miscellaneous...	1055	10.3	102.0
Net Coke.....	1782	59.4	30.0
Gross Total.....	6903	102.1	67.5
Less Flue Dust Produced.	284	2.6	110.0
Net Total.....	6619	99.5	66.5
Iron production, net tons per day.....			1,324
Cubic feet materials processed per day.....	$1,324 \times 99.5 =$		131,738
Working volume, cubic feet.....			44,849
Furnace fillings, number per day.....	$131,738 \div 44,849 =$		2.94
Time material in furnace, hours.....	$24 \div 2.94 =$		8.16
Working height, feet.....			79.52
Speed of material descent, feet per hour.....	$79.52 \div 8.16 =$		9.75

In the above calculations, the weights of ore per cubic foot used are less than the weights as they lie in the pile, due to the ore being "fluffed up" in handling.

Furnace Linings—The brickwork which forms the hearth, bosh, and inwalls of a furnace is referred to as its lining. All the brick used in the construction of these parts are made of fire clay. The brick in the hearth and bosh are required to resist a very high temperature and the action of flux and slag; brick in the inwall zone must be able to withstand abrasion at a moderately high temperature; and top brick, though always at a comparatively low temperature, must resist the impact and abrasive forces of the charges as they are dropped into the furnace.

The bricks are inspected carefully before being put in place in the furnace. Great care is exercised with respect to brick, because the life of the furnace depends in a large measure upon the lining, and the item of cost for brick is not a small one. In the construction of one of the large thick-wall furnaces, the equivalent of ap-

proximately 1,000,000 nine-inch bricks is required. Fire-bricks are always laid in a thin slurry composed of refractory mortar. The slurry is applied by pouring it on the top of each course with a dipper, and followed immediately by the next course of bricks, which is hammered into place to squeeze out all the fire clay except that required to compensate the inequalities of the brick.

Water Troughs—Encircling the furnace bosh, at about the level of the bustle pipe, will be found one or more water troughs into which the water supplying the numerous cooling plates is discharged in visible streams, thus providing means of determining when a plate, tuyere, or cooler is burned out. The water, flowing from these troughs into a well, may be reused by pumping to the condensers or gas washers. The better practice is to reuse the water from the condensers for furnace cooling.

Top—At the present time furnace tops are somewhat complicated affairs. In olden times the tops of furnaces were left open, the escaping gases being allowed to burn in the air. In the year 1809, these waste gases began to be employed in France for the purpose of burning bricks and heating small furnaces. The first attempt to heat the blast by utilizing these gases was made in 1829. It was not until 1845 that a plan was evolved by which the gases could be used to heat "stoves", which are separate structures designed for the sole purpose of preheating the air blown into the furnace through the tuyeres; these are described later. To effect this purpose, changes in top construction were necessary. At first the gases were merely drawn off by the chimney draft of the stoves through openings below the stock line. The arrangement, known as the bell and hopper, or cup and cone, was not put into use until 1850. It consisted in finishing the top of the furnace with a large circular hopper, the smaller opening of which was closed by the bell that could be lowered and raised at will. With the bell raised against the hopper, the materials were dumped into the hopper; then when the bell was lowered, the charge dropped into the furnace. As large quantities of gas escaped with each lowering of the bell, this device was improved by the double bell and hopper, which is of comparatively recent origin. Essentially, this improvement consisted in placing a second but smaller bell and hopper above the first, and providing a gas-tight space of large size between the two. The raw material, upon being hoisted to the top, is first dropped or dumped into the upper hopper, whence it may fall into the larger hopper below when the small bell is lowered. The small bell being raised against the upper hopper, the large bell is lowered, and the charge falls into the furnace without the escape of gas. The bells are made of cast steel, in one piece, and of such a slope, 45° to 55°, as to permit the charge to slide off readily. They usually are supported from their top centers by a rod and a sleeve, each attached to a counterbalance lever operated by a steam or air cylinder or an electric motor, controlled from the ground. The large bell is attached to the rod and the small bell to the sleeve. The hoppers, of cast steel or iron, generally are made up in sections, which are securely bolted together. The details of this construction differ somewhat from furnace to furnace to conform to the introduction of improvements, with the type of hoist, and with the preferences of the different builders. Operation of a typical design is shown in Figure 12-7.

Hoisting Appliances—The old-time method of charging by hand having been superseded by mechanical charging, there are now in use two types of these devices, namely, the skip hoist and the bucket hoist. In

FIG. 12-7. Diagram of progressive steps by which the double bell and hopper permits charging raw materials into a blast furnace without escape of furnace gases.

FIG. 12-8. Overall view of a blast-furnace plant, showing two furnaces and the stoves that operate in conjunction with them.

PRINCIPAL OPERATING PARTS OF A BLAST FURNACE TOP*

* THE VARIOUS PLATFORMS AND STRUCTURES SUPPORTING THE TOP EQUIPMENT HAVE BEEN OMITTED FROM THIS DRAWING, AS WELL AS THE CABLES AND SHEAVES THAT OPERATE THE SKIP AND BELLS. ALSO OMITTED ARE THE JIB BOOM CRANES THAT ASSIST IN HOISTING REPAIR AND REPLACEMENT PARTS TO THE TOP OF THE FURNACE.

FIG. 12-9. Principal operating parts of a blast-furnace top.

both cases there is an incline (a fabricated steel structure) extending from the top of the furnace to or below the bottom of the stock house; and over the tracks of this incline the materials charged into the furnace must pass. In the **skip hoist**, the conveying vessel is a small open-ended steel car, called a **skip**, that automatically dumps the materials into a hopper above the small bell. Skip hoists are generally provided with double tracks, so that while a loaded skip is passing up the incline an empty one is descending. In the **bucket hoist** the solid materials are raised in a bucket, suspended from a truck or carriage, that drops the charge directly into the space above the large bell. When in position for dropping the charge, the bucket, being itself provided with a small bell at the bottom, takes the place of the little bell and hopper. While the bucket is being filled at the stock house, the opening left in the top is closed with a special gas seal. Figure 12—8 shows furnaces equipped with skip hoists.

Top Appliances for Distributing the Stock—It is apparent that, in a mechanically filled furnace, when the raw materials are dropped into the receiving bell, the larger lumps of ore and stone will have a tendency to roll and thus collect around the edges, or perhaps at one side or the other. The same segregation, if uncorrected, will also occur upon dropping the charge into the furnace. This tendency results in more or less open and continuous **channels** being formed through the materials and extending from the top towards the bottom of the stack. These channels offer less resistance than the remainder of the materials to the passage of gases through the furnace, with the result that a disproportionately large quantity of gas passes through them. This condition, called **channeling**, also results in excessive temperatures along these passages. To overcome this defect, various plans and devices have been employed to introduce the materials into the furnace in such a way that this segregation of coarse and fine material will not occur.

Rotation of the position of the charge on the large bell by various means has been most effective in minimizing channeling. This can be accomplished in several ways, depending upon whether the furnace is bucket or skip charged. One of the most popular and effective devices is a rotating hopper above the small bell which can be rotated through a prescribed arc before the small bell is lowered.

Some designers concentrate upon details of construction of the furnace top and of the large bell and hopper with good results. For example, it can be shown that as the diameter of the large bell approaches the internal diameter of the furnace top, the fines are concentrated next to the wall, and as the bell diameter is decreased, a dimension is reached that throws some lumps against the wall and some toward the center, while a further decrease in diameter throws more and more lumps toward the wall until all the fines are concentrated at the center. Other factors, such as the angle of the bell, the angle of the hopper, the extension of the bell below the hopper, the distance below the hopper the bell can be dropped, and the speed with which it can be lowered, all may be adjusted to produce the best charge distribution.

Top Openings—The smallest opening in the top of a furnace is the **try hole**. In operating a furnace it is necessary to be able to determine the position of the stock line. This is done by means of the **stock indicator**, which is a rod of steel passing through and fitting the try hole loosely so that one end rests upon the stock, while the other is attached to a small steel cable that leads to the stock house or the cast house below. Some stock indicators are automatic and self-recording. Some modern furnaces use two stock indicators, mounted 180° apart.

Gases resulting from the smelting operation are conducted to the top of the furnace by large, vertical pipes called **offtakes**, each of which is about 6 feet in diameter. The offtakes, usually four in number, are connected to openings in the furnace top at about the level of the big hopper. They may be constructed either of abrasion-resistant steel or may be lined with firebrick. The tops of the offtakes are connected in pairs, and pipes lead from these connections into one large descending pipe called the **downcomer** or **downtake**. Rising above the junctions of each pair of offtakes are tall, vertical pipes called **uptakes** or **bleeders**. These usually are lined with one course of firebrick. The tops of the bleeders are equipped with counterweighted valves. These valves have a double purpose: first, they may be opened by mechanical means from ground level to permit surplus gas to escape from the furnace system; secondly, they may be adjusted, either by weights or mechanical means, to act as **explosion doors** and open at a predetermined pressure to relieve sudden increases in gas pressure occasioned by "slips" in the furnace, and thus prevent possible injury to the top. A third bleeder, with explosion door, may rise above the junction of the pipes from the offtakes with the downcomer (Figure 12—9). Some furnaces have a separate bleeder for each offtake. The explosion doors are at the highest point of the furnace (Figures 12—8 and 12—9).

General Considerations for Top Construction—As previously pointed out, there are many types of tops, and the description above is intended to give a general idea of the essential parts and their uses. The chief endeavor in top construction is to perfect the distribution of the stock entering the furnace stack, and either eliminate or compensate for as many irregularities as possible, while a second aim is to hold to a minimum the amount of solids (coarse and fine dust from the raw materials) carried out with the gas. However, in attaining these ends, simplicity must be considered, as any great amount of mechanism on the top of a furnace is objectionable. It is important to prevent large material from being thrown out of the furnace in case of slips, and as little dust as possible at any time should be carried out by the gases. In locating the offtakes, care is taken to see that they do not enter the furnace directly over the tapping hole, cinder notch, or the entrance of the blast main to the bustle pipe, because, these being the most active points in the furnace, entering the furnace over these points would tend to cause more uneven distribution of the gases through the stock. In the latest furnaces, the top diameters have been increased in an endeavor to reduce the relative amounts of flue dust produced.

SECTION 4

CONSTRUCTION OF FURNACE AUXILIARIES

Stoves—Blast-furnace stoves, usually three per furnace, are brick-lined regenerators enclosed in a circular steel shell with a flat bottom and a dome-shaped top.

Their function is to preheat the blast before its admission into the furnace through the tuyeres. The result of preheating the blast is to intensify and speed

up the burning of the coke at the tuyeres with a consequent reduction in the coke required for the smelting operation; this reduction in coke consumption is more than would correspond merely to the additional sensible heat carried in by the heated blast. Essentially, a stove consists of two parts; the first being the combustion chamber which is a vertical passageway (in which cleaned blast-furnace gas is burned) extending from a point near the bottom of the stove to the bottom of the dome, and through which the hot products of combustion pass upward to the dome. The second main part is the checkerwork, which contains a multiplicity of small passageways through which the products of combustion from the blast-furnace gas pass downward from the dome to a point near the bottom of the stove. This description applies to the two-pass design which is the most prevalent today but there still exist quite a number of stoves of the three-pass design, the difference being that an additional upward pass of checkerwork is added through which the products of combustion pass before their exit at the top of the stove. In a few rare cases, a four-pass design has been used which again simply adds a downward pass for the products of combustion over the three-pass design. In all designs, there is only a single combustion chamber. The two-pass design offers a larger percentage of the cross-sectional area for checkerwork than either the three- or four-pass designs because of the space taken up by the walls which separate the passes. With sufficient volume of checkerwork installed, the two-pass design permits the spent gases to leave the stove at a temperature no higher than that from stoves with the more complicated and more costly three- and four-pass designs. The temperature of the exit gases is, of course, a measure of the efficiency of the stove. The design of stoves may be broken down further into either the side-combustion or the center-combustion types, which refers to the location of the combustion chamber inside the shell itself. The preference seems to be for the side-

combustion type. Figure 12—10 shows vertical and horizontal sections for the side-combustion type.

Modern stoves for large furnaces are 26 to 28 feet in diameter and about 120 feet high from the bottom of a stove to the top of its dome. Depending upon the type of checkers used, the stoves contain between 250,000 and 275,000 square feet of heating surface. If the checkerwork walls are too thin, structural failures will result. It has been found that a ratio of weight of brick (in pounds) to square foot of heating surface of about 10 is the minimum. Below this ratio structural difficulties are encountered. Formerly the checkerwork was supported several feet above the bottom of the stove by brick piers but present construction uses cast-iron or steel columns to support steel grids which in turn carry the checkerwork. Insulation between the brick and the steel shell prevents the heat in the stove from distorting the steel plates. The blast-furnace gas used to heat the stoves is cleaned almost universally by wet washing, primarily in a tower-type washer and finally in a precipitator or disintegrator. Primary gas will contain about 0.2 grain per cubic foot of solids and should not be used in stoves with openings less than $4\frac{1}{2}$ in. square. Final or secondary gas will contain less than 0.02 grains per cubic foot and can be used successfully in checkerwork with openings slightly less than 2 inches by 2 inches. An empirical factor of about 500 square feet of total heating surface per net ton of daily furnace production has been found to give adequate stove capacity. This excludes the area of any cross flues in the checkerwork.

The stoves for a furnace, when of the two-pass design, usually are provided with a common stack about 200 ft. high, while three-pass stoves have an individual stack for each stove mounted on top of the dome of the stove shell.

Air blast for the furnace passes through the heated stove in a manner counter-current to the passage of the gas. In a two-pass stove the gas passes upward through

Checkers of this type are designated as of basket weave with inserts, as shown in detail at left of Figure 12—11.

FIG. 12-11. Five different designs of checker-building shapes employed in the construction of modern blast-furnace stoves. The basket-weave design with inserts is shown in Figure 12-10 also.

the combustion chamber, downward through the checkers, and out to the stack while the blast passes upward through the checkers, downward through the combustion chambers, and out into the hot-blast main. With three stoves to a furnace, one stove is "on blast" at a time while the other two stoves are "on gas" with the result that each stove is "on gas" twice as long as it is "on blast." In order to accomplish the changeover from gas to blast, and vice versa, certain valves are necessary.

The hot-blast valve is usually of the water-cooled mushroom type, closing on a water-cooled seat. Its function is to open the passageway for the heated blast from the combustion chamber to the hot-blast main. The cold-blast valve admits cold air from the blast line into the space directly below the checkerwork and, not being subjected to high temperatures is usually of the gate type. The chimney valves, usually two in number, open and close the passageway for the products of combustion from the stove to the stack and are subjected to only moderately high temperatures. The blow-off valve releases the pressure in the stove when changing the stove from "on blast" to "on gas." Since the heated blast leaves the stove at a higher temperature after the stove has just been put "on blast" than after it has been cooled somewhat by the air undergoing heating that passes through it, and since it is desired to maintain, in most cases, the hot blast at a constant temperature, the mixer valve by-passes a certain amount of the cold blast into the heated blast and by its regulation maintains a constant hot-blast temperature. A pyrometer is installed in the hot-blast line beyond the point of entry of the mixer line; it can be set to the temperature desired and will operate a mixer valve automatically to maintain this temperature. The burner valve or door opens and closes the passageway from the stove gas burner into the combustion chamber. Most gas burners

today are of the pressure type, in which the air for the combustion of the gas is blown by a fan into the burner in such quantities as to give theoretically perfect combustion. In the older type burners, the combustion air was aspirated into the combustion chamber with the gas with resultant mediocre combustion. The nose of the burner is movable so that it may be moved tightly against a flange on the burner door to prevent any infiltration of air or puffing out of the gas when the stove is "on gas." Inspection or cleanout doors are provided at the top and at the bottom of the stove. The snort valve, which derives its name from the noise made by blast escaping into the atmosphere, is located in the cold-blast line leading from the blowing room to the stove. Its function is to relieve the pressure of the blast entering the furnace when a "slip" occurs in the furnace, during casting, or when any emergency occurs. It consists of two interconnected butterfly valves, one closing the line against the blast, and the other opening a by-pass line to the atmosphere.

The brick lining of a stove, which includes all the brickwork enclosed by the shell, usually lasts from 15 to 20 years before it becomes necessary to replace it because of spalling, deformation, or clogging of the checkers. In addition, it may be necessary to replace the upper 10 to 20 feet of the checkerwork at the end of each furnace campaign, or from five to seven years. An insulating space of about 3 inches between the brickwork and the steel shell is filled with high-grade loose insulation or insulating strips. The bottom is insulated with insulating concrete, and the dome is covered by small insulating squares on top of which loose insulation is placed. The dome of a modern stove is separately supported from the outside of the shell, which allows the brickwork below to "breathe" and at the same time permits replacement of the lower brickwork without disturbing the dome (see Figure 12-10).

The brick is first-grade firebrick and should possess high thermal capacity and conductivity. The skin wall of the combustion chamber and the top 10 feet of checkerwork are constructed of a higher alumina brick than first-grade firebrick. Some designers prefer semisilica brick, made from New Jersey clay, over the higher alumina brick. Formerly, checkers were built of the conventional rectangular formed brick and provided relatively large channels for passage of gases. With the advent of the use of secondary-cleaned gas in the stoves, the use of smaller openings has become feasible. Inserts may be used in the passages of checkers built of rectangular brick, as shown in Figure 12-10, or special brick made in clusters with each cluster containing several openings may be used; the latter facilitate laying and handling. Figure 12-11 shows several types of the more common clusters now in use. The thermal efficiency of a stove is about 85 per cent. The stoves use between 18 and 24 per cent of the gas produced by the furnace for heating the blast.

Dustcatcher and Gas Mains—The object of the dustcatcher is, as implied by its name, to remove as much as possible of the flue dust blown over from the furnace, with which the gas is heavily laden. If this dust is not removed, at least in part, it puts an unnecessary load upon the primary and secondary washers and, in addition, the dust is more easily and economically handled in the dry state as it comes from the dustcatcher. The dustcatcher is from 35 to 40 feet in diameter, usually lined with brick to prevent cooling and the attendant precipitation of water from the gas. It is a cylindrical structure fitted with a 60-degree inverted cone on the bottom and a cone-shaped top.

The single downcomer from the top of the furnace carries the gas to the top of the dustcatcher, where it enters a vertical pipe that is centrally located inside the dustcatcher and extends nearly to the bottom (Figure 12-2). This vertical pipe flares outward about 8 degrees and is thus larger in diameter at the bottom than at the top. As the gas passes downward through this pipe, its velocity (and therefore its ability to carry dust) is lowered, causing some of the dust to drop out of the gas stream and be deposited at the bottom of the dustcatcher. When the gas emerges from this pipe, it must change direction of flow suddenly and rise to the top of the dustcatcher, since the gas is removed from a convenient location at the top. The sudden change in flow direction causes more dust to be dropped from the gas stream. Efficiency of the dustcatcher is approximately 60 to 75 per cent, depending upon the type of ores used and the blast volume. The accumulating dust usually is removed from the dustcatcher by a double-shaft pug mill which is rigidly fastened to the cone bottom. Water is added to the pug mill until the dust is slightly moistened, which prevents the dust from blowing around the vicinity as it drops into a railroad car. An auxiliary hand-operated gate also is provided which permits dust to be removed in case the pug mill is down for repairs. The exit gas passes from the dustcatcher into the bottom of the primary washer.

Gas-Cleaning Plants—Neglecting the larger lumps blown out occasionally when the furnace "slips," the dust particles in blast-furnace gas vary in size from $\frac{1}{4}$ inch to a few microns (1 micron = 0.00003937 inch) with practically all of the dust passing the dustcatcher being minus No. 20-mesh sieve size. The difficulty of cleaning increases as the particle size decreases, the removal of the very fine particles being comparable to the removal of smoke from air. On this account, plants generally are planned to clean the gas in two stages, a **primary stage** to remove the coarser particles, which

form the larger proportion of the dust, and a **secondary** or **final stage** to remove as much of the remaining dust as possible. The approximate removal of incoming dust by the usual gas-cleaning system is 60 to 75 per cent in the dustcatcher, 90 to 95 per cent of the remainder in the primary washer, and 90 to 95 per cent of the dust still in the gas leaving the primary washer is eliminated in the secondary washer. The gas entering the dustcatcher contains from 7 to 30 grains per cubic foot, an average dust content being about 16 grains per cubic foot. In some cases, a centrifugal cleaner is installed between the dustcatcher and the primary washer.

Either of two methods is used to clean the gas passing the dustcatcher, wet cleaning or dry cleaning. In **wet cleaning**, the aim is to wet the dust particles and wash them out of the gas with water. Incidentally, the gas is cooled to about the temperature of the wash water, and any moisture in excess of saturation at this temperature is precipitated. In **dry cleaning**, one of the aims is to remove the dust without cooling, thus conserving the sensible heat. In many cases, the temperature of the gas leaving the furnace is under 300° F (150° C) as contrasted with 500° F to 600° F (260 to 315° C) in former practice. The elimination of the water, which exists in the gas as superheated steam, and which is reduced to its dew point concentration at the cleaning-water temperature, more than balances the loss in sensible heat in wet cleaning. For these reasons, dry cleaning presently is not used to any great extent.

Primary wet cleaners include stationary-spray towers, revolving-spray towers, Feld washers as described later, baffle towers, spray fans and water separators. The stationary-spray tower is most used, although many Feld washers remain in use, and, sometimes a washer consists of a combination of one or two Feld washer revolving cones in the bottom, above which are several banks of stationary sprays. In almost all cases, a water separator is mounted on top of the washer as an integral part thereof.

The **stationary-spray tower** consists of a supported steel cylinder with conical bottom and conical top with the gas entering at a point near the bottom of the cylinder and leaving through a centrally located outlet on top of the top cone. Inside the cylinder are three or four banks of ceramic tile (with about 5-inch diameter round holes in them) which split up the rising gas and tend to prevent channeling. Above each bank are water sprays which uniformly cover the cross section of the washer with a falling "rain." A U-shaped seal pipe at the outlet of the bottom cone carries the dirty water away to a Dorr thickener or settling basin and prevents the gas from blowing to the atmosphere. A centrifugal-type water separator above the topmost bank eliminates any entrained water in the outgoing gas.

The **Feld washer** is a cylindrical shell with a flat bottom and a conical top in which there is a series of from 5 to 7 inverted frustrums of cones which rotate on the same centrally-located vertical shaft, driven by a motor and reduction gear on top of the washer. The lower edge of each cone is immersed in a separate water tray. The centrifugal action of the rotating cones picks up water from each tray and throws it outward toward the shell as a spray through which the rising gas must pass. Baffles guide the water back into the trays for reuse, excess water spilling into the next tray below. A water separator similar to that on the stationary-spray tower is located above the topmost rotating cone.

Primary dry cleaners include various modifications of cyclone separators, centrifugal machines, metallic-wool-pad filters, and electrical or Cottrell precipitators. The dry-type Cottrell precipitator may also be classed

as a secondary dry cleaner and will be discussed under that heading. The cyclone and centrifugal types present the problems of excessive wear and difficulty in handling the fine dust removed. The filters have a tendency to clog shortly after being placed in operation.

Secondary wet cleaners have consisted of wet-type Cottrell precipitators, high-speed disintegrators, and Theissen disintegrators. Formerly, Theissen disintegrators were used almost exclusively, but on later installations have been replaced by high-speed disintegrators or by the wet-type Cottrell precipitators, with preference being given to the latter type. The Theissen disintegrator is a type of fan that dashes water, introduced through small jets, into a spray which is forced to travel in one direction while the gas is forced through the same channels in an opposite direction.

The high-speed or rotary disintegrator is a smaller diameter machine than the Theissen but rotates faster (500 to 700 rpm) and consists of a casing in which is mounted a rotating "squirrel cage." This cage is made up of two heads fastened to the shaft with a series of bars parallel to the axis fastened to the heads. Vanes mounted on the heads reduce the pressure-drop through the machine and force the incoming gas through the rotating bars, upon which water is sprayed, to the center of the cage where it is taken off to the clean-gas main. These machines are built up to 40,000 cu. ft. per min. rated capacity, require from 400 to 500 horsepower to drive them, and will clean the gas to under 0.02 grains per cubic foot.

In the Cottrell wet method of cleaning, the primary-cleaned gas is forced to pass through narrow channels or ducts across which an electrostatic field is maintained. The dust particles are "precipitated" or separated from the gas through the action of electrostatic charges. The molecules of gas are ionized and, in turn, induce electrostatic charges upon the surfaces of the small dust particles. Under these conditions, the dust particles are attracted toward the electrode of opposite polarity. There is also an "electrical wind" or corona effect. Current is supplied from an alternating-current source, stepped up in voltage by a transformer, and made unidirectional by a mechanical rectifier or by vacuum tubes. In most precipitators cleaning cool gases, the unit collecting electrode is a vertical tube, 8 to 12 inches in diameter, or it may be of parallel steel plates through which the gas is forced upward, or sideways. In the former type the discharge electrode is a wire suspended coincident with the long axis of the tube and, in the latter, multiple wires midway between the plates. A thin film of water flows over the inside edge of each tube or plate which washes it free of dust that has been deposited thereon, the dirty water being conducted to a Dorr thickener or settling basin. The precipitator usually is divided into two units with valving so arranged that one unit may be shut down for inspection or repairs while the other unit is operating. In some installations, the precipitator is mounted directly above the primary washer. The rotary disintegrator has the advantage of lower first cost but has higher power cost than the wet-type Cottrell precipitator. The cleanliness of the gas may be slightly in favor of the precipitator.

Secondary dry cleaners have included bag filters and Cottrell precipitators. The bag-type filters, sometimes called the Halberger-Beth type, consist of a number of fabric "socks" made of cloth, glass threads, asbestos threads, or very fine Monel metal screen (or a combination), supported at the top and closed on the bottom, into which the gas passes from the outside forming a film of dust on the sock which acts as the filtering

medium. When the film of dust becomes too thick, the exit end of the sock is closed thereby shutting off the gas flow and the sock is shaken or vibrated to drop the excess dust into a collecting hopper. The socks are stiffened both circumferentially and longitudinally to prevent their collapse. It has been difficult to find a fabric which does not break down under the temperature encountered with hot blast-furnace gas. Also, if the temperature of the gas should reach its dew point, moisture would deposit in the fabric thereby forming a deposit of dust on the sock which cannot be dislodged.

The dry-type Cottrell operates upon the same principle as the wet type but is constructed somewhat differently. The modification consists in using slabs of reinforced concrete as collecting electrodes to form channels for the passage of the gas, with the discharge wires suspended along the center lines of the channels. Periodically, each unit is taken out of circuit to permit the dust on the collecting electrode to fall into a hopper below. In this type, the dust is detached from the collecting electrode by suspended chains which are used as scrapers and which are operated by air cylinders. The dry-type precipitator has not cleaned the gas to the cleanliness required for small-checker stoves, gas engines, or for underfiring of coke-oven batteries.

Wash-Water Disposal—The water used to clean the gas in the wet-cleaning system contains about 40 per cent of the dust recovered, the other 60 per cent being recovered in the dry state. The wash water from all units is gathered together and conducted to a settling basin or thickener, present preference being given to the thickener. The usual settling basin is rectangular in plan and divided into two units so that one may be filling while the other is being emptied by a tractor or locomotive crane or by a permanent overhead crane. Each unit consists of several weirs over which the water flows in series, depositing a portion of the solids in each compartment. When one unit is full the water is then switched to the other unit and the full unit emptied. The handling of the wet solids into railroad cars is a difficult task, both at the basin and in the vicinity, due largely to the inability to make the railroad cars water tight.

A typical thickener consists of a circular, reinforced-concrete tank which may contain one or several compartments in each of which one or several arms revolve. The arms are driven from a central vertical shaft. Water enters at the center of the thickener and leaves over a continuous weir which follows the circumference of the compartment. Each arm carries a series of rakes or vanes set at such an angle that the solids which settle out are gently pushed toward the center of the compartment. The thickened solids, containing about 60 per cent water, are pumped out and delivered either pneumatically or by pump to a filter for further processing. The thickener may be built with either an open or closed top. Two types of filters are in general use, the cylindrical or drum type and the disc type. Both operate upon the underflow from the thickener, discharged into a basin into which an arc of the slowly rotating filter dips. The drum or disc consists of a framework over which canvas is stretched, and a partial vacuum is applied on the inside of that part which dips in the basin, thereby drawing the liquid through the canvas while the solids are retained by the canvas. When the drum or disc reaches another point in its rotation, a slight air pressure is applied on the inside of the canvas thereby bulging it and causing some of the filter cake to crack and drop off into a chute, the balance being scraped off by a scraper. The filtrate returns to the thickener and the filter cake, containing

about 25 per cent moisture, is delivered by railroad car to the sintering plant or, if the sintering plant is located adjacent to the furnace, the filters are designed as an integral part of the sintering plant itself.

Sintering Plant—A sintering plant's primary function is to agglomerate the flue dust and filter cake produced in the operation of the blast furnace into a product more acceptable for recharging into the furnace, and its secondary function is to beneficiate some of the finely divided ore. As the supply of high-grade ore is depleted, the secondary function may transcend the primary function and for purposes of description it is assumed that part of the charge contains a portion of fine ore for beneficiation. Modern sintering methods and equipment already have been described in Chapter 6 on iron ores, along with other methods of agglomerating fines.

Cast House—Since the molten iron is heavier than the slag or cinder, it lies in the bottom of the hearth and is cast or removed 4 or 5 times a day through the iron notch. This is an opening which is plugged with clay except when the furnace is casting. The usual method of casting is to drill into the clay with a pneumatic drill until the skull of iron is met, when an oxygen lance is used to burn through the iron skull. The iron flows into the main trough which has a skimmer located near its end. The skimmer separates any slag flowing with the iron and diverts it into the cinder ladles or to the cinder granulating pit. The iron continues to flow down the main runner from which it is diverted at intervals into the iron ladles, the control of this operation being accomplished by gates or shutters located in the runners (Figure 12—12).

The closing of the hole at the finish of the cast is accomplished by means of the **clay gun**. The gun is swung from an arm mounted on a pedestal in the cast house or on one of the furnace columns. It consists of a cylinder narrowed to a nozzle at the exit end and a capped opening on top into which soft clay is placed preliminary to casting time. The arm is normally parallel to the main trough but when placed in operation the arm is swung through 90° and the gun is tilted so that the nose enters the iron notch. The clay is forced from the gun by a plunger or screw; the plunger usually is operated by steam and the screw by an electric motor. Figures 12—13 and 12—14 show a typical clay gun.

The slag is flushed from the furnace through the monkey two or three times between successive casts and it flows through runners, in much the same way as the iron, into cinder ladles, into a granulating pit, or into a slag machine. The monkey is closed by pushing into the hole by hand, a steel, cone-shaped knob on the end of a long steel bar, called the **cinder bott**, or this may be accomplished mechanically by arms attached to a framework which supports and guides a water-cooled bott (Figure 12—15).

Iron Disposal—Iron ladles are of three types: the open-top ladle, the Kling-type ladle, and the mixer or Pugh-type ladle, all of which are refractory-lined. The **open-top ladle**, as the name implies, is an inverted frustrum of a cone with the top open to the atmosphere. The maximum capacity of this type is about 75 tons. The ladle is supported on the car or carriage by trunnion castings on the ladle, resting in corresponding castings on the car. In all types, the car usually is equipped with

FIG. 12—12. General view inside the cast-house of a blast-furnace plant.

FIG. 12-13. Automatic clay gun, ready to be swung into position for closing the tap-hole of a blast furnace at the end of a cast. Clay is ejected under pressure from the nose of the gun, which is inserted in the tap-hole (see below).

air brakes and automatic couplers. The Kling type is somewhat spherical in shape with an opening at the top through which the iron enters. Its advantage is less radiating surface with consequent less skull formation. It is built up to about 115 tons capacity and is supported on its car similarly to the open-top ladle. The Pugh-type ladle is cigar-shaped with an opening at the top. It is built up to 200 tons capacity and differs from the other two types in that it is not removed from the car, the ladle itself forming part of the car between trucks. To empty the Pugh ladle, it is rotated about its longitudinal axis and, due to its large capacity in relation to the opening, offers the least radiating surface. In some cases, this type ladle functions as a metal mixer and the regular mixer is eliminated, with the iron going directly from the mixer ladle to the steel-making process. A

ladle of the Pugh type is shown in Figure 12-16.

Normally, the iron ladles carry the molten iron to the metal mixer but there are times when it is necessary to dispose of the iron by casting it over the pig machine. Present pig machines differ only slightly from each other;—the chain in one type carrying rollers on each side that ride on a track; while, in the other type, the sides of the chain form a track which rides on stationary rollers. The endless chain, carrying a series of parallel cast-iron molds or troughs with overlapping edges, passes over a head and a tail sprocket wheel. The molten iron is poured into the molds near the tail sprocket, solidifies, and is cooled by water sprays as the chain rises to the head sprocket, and falls from the molds into cars as the chain passes over the head sprocket. On the return travel of the chain, the molds are sprayed with a

FIG. 12—17. Ladle pouring molten iron into traveling molds of a pig-casting machine.

lime wash to prevent sticking of the iron to the molds but, in cases where the pigs do stick to the molds, a "pig sticker" at the head end loosens the pig from the mold. Most machines are of the double-strand type, that is, they are built with two parallel chains. In the operation of the machine, iron is poured from the ladle into a small basin, which reduces the splash and which then divides the stream of molten iron to serve the two branches, one for each chain. The speed of travel of the chains and rate of pour of metal from the ladle are controlled so that a full-sized pig is formed in each mold. Pigs for use in the steel mills weigh almost 100 pounds but, for some commercial uses, pigs weighing as little as

30 pounds are poured. Operation of a pig machine is illustrated in Figure 12—17.

Slag Disposal—The slag is handled in one of four ways: it flows directly into cinder ladles; it is granulated; it flows directly into cooling pits; or it is made into lightweight aggregate for concrete or insulation. The cinder ladles are unlined, tulip-shaped, cast-iron (sometimes steel) pots mounted on cars or carriages on which they are moved from the furnace to the slag dump. The cars are equipped with air- or steam-operated cylinders which partially rotate the trunnion holding the ladle so that it can be dumped by the compressed air in the railroad train line (Figure 12—18).

FIG. 12—18. Molten slag pouring from runners in floor of cast house into cinder ladle.

THE BRIDGE MOVES ALONG THE TRACKS PARALLEL TO THE DOCK WALL TO BRING THE CARRIAGE DIRECTLY OPPOSITE TO A HATCH OR OPENING IN THE DECK OF THE ORE BOAT. THE CARRIAGE ADVANCES ALONG TRACKS ON THE BRIDGE TO BRING THE OPEN GRAB BUCKET DIRECTLY OVER THE HATCH.

THE RIGID LEG SUPPORTING THE GRAB BUCKET IS LOWERED BY TILTING THE COUNTERWEIGHTED ARM UNTIL THE GRAB BUCKET CONTACTS THE ORE PILE IN THE HOLD OF THE ORE BOAT.

THE GRAB BUCKET IS CLOSED, TAKING A "BITE" OF UP TO 20 TONS OF IRON ORE.

THE COUNTERWEIGHTED ARM RAISES THE LOADED GRAB BUCKET OUT OF THE HOLD OF THE ORE BOAT.

THE CARRIAGE MOVES BACK TO PERMIT THE GRAB BUCKET TO DISCHARGE ORE INTO A STATIONARY HOPPER ON THE BRIDGE. GATES OF THE HOPPER OPEN TO DUMP ORE INTO A DUMP-BOTTOM TRIPPER CAR WHICH CARRIES THE ORE EITHER TO RAILROAD CARS OR TO THE ORE TRENCH, WHILE ANOTHER "BITE" IS BEING TAKEN BY THE GRAB BUCKET.

FIG. 12-19. The sequence of operations of a Hulett unloader transferring iron ore from the hold of an ore boat to railroad cars or storage areas on the dock.

Sometimes the molten slag, if of suitable composition, is dumped in specially prepared dumps, from which it is removed by a power shovel (after weathering for a period of several weeks), screened, and sold as an aggregate for concrete or as ballast. In granulating slag, provisions are made for the molten slag to strike a stream of high-pressure water as it falls from the lip of the runner, forming a popcorn-like mass which later is loaded onto cars by grab bucket. In this form, it is used in the manufacture of cement. Some of the newer furnaces flush the slag directly in long, rectangular, concrete walled pits, open at one end, from which it is removed by a power shovel and loaded into railroad cars. The pits are usually two in number, one being filled while the other is being emptied, with from five to seven days being required to fill a pit. In this form the slag, after screening, is used as an aggregate for concrete. In a few cases, the slag as it flows from the runner is met by a small stream of water, steam, air, or a combination of these which partially granulates it, but with no excess water, so that the product formed consists of lumps which are filled with air cells. After screening out the fines, the product is used for insulation or, when cement is added, as a lightweight concrete. By adaptation of the method used, it is sometimes possible to make slag disposal a profitable operation.

Handling Ore from Vessel—The ore used in many furnace plants is mined at considerable distance from the plant and requires transportation either by rail or water, or a combination of both, before reaching the plant site. Coke and limestone, the other essential ingredients, are rarely stored in large quantities and are consumed as currently received. In the case of ore, weather conditions are often such as to prevent mining and transportation during the colder months so it is necessary to store during the warm months approximately half a year's supply adjacent to the furnaces. Since many of the furnaces in this country receive their ore from the Lake Superior District, as discussed at length in Chapter 6, the transportation of ore from there is described very briefly here as being typical of water transportation of ore. Ore, at the head of Lake Superior, is loaded by gravity, from long piers extending into the harbor and carrying overhead bins, into specially constructed ore boats capable of carrying up to 20,000 net tons of ore per trip. These boats have a speed of 12 to 15 miles per hour and a draft of 20 feet. Upon reaching their destination, the ore is unloaded by Hulett unloaders or by special unloading rigs if the plant is large enough to justify this special equipment, or, if the plant is smaller, by an ore bridge which extends over the vessel and permits the ore-bridge bucket to unload the vessel.

The Hulett unloader (Figure 12—19) consists of a carriage mounted on wheels which permit it to move in and out in a direction at right angles to the dock, and which carries a counterweighted pivoted arm, on the harbor side of which is located the grab bucket capable of handling 20 tons at a time. The operator rides in a compartment near the bucket and controls its movement from this location. The bucket itself can be rotated, and the entire unloader can be moved parallel to the dock. The bucket moves downward through the open hatch of the vessel, takes its "grab," and then moves upward and backward depositing its grab into a hopper. Under the hopper is a rotating feeder which places the ore into a small car that runs backward either to a hopper over railroad cars or to an ore trench in the ore yard. The ore bridge picks the ore from the ore trench and distributes it onto the ore pile.

The unloading rigs perform the same function as the

Hulett but differ somewhat in construction. Instead of the bucket being carried by a rigid arm, it is hung from a trolley resembling a crane trolley; consequently, it cannot be rotated and it cannot clean out the hold of the vessel as completely as the Hulett, and the additional use of a small bulldozer and hand labor is necessary to complete the job.

Car Dumper—For those plants located some distance from the point of vessel unloading, or where ore is received directly from the mines by railroad, a car dumper is the usual means used to unload ore. The ore, arriving at the plant in trainload lots, is switched to a siding ahead of the car dumper and the cars are unloaded one by one in rapid succession. A car, being pulled up an incline to the platform of the dumper by a steel cable of a "mule" or "barney," is lifted bodily and turned over so as to empty its contents into a large transfer car which, in turn, discharges into an unloading trough opposite the location in the stock yard for that particular grade. The dumper then resumes its former position and the empty car is pushed off the platform, by the next car of ore, to an incline, down which the empty cars move to a siding. The transfer cars are usually designed to hold two railroad cars of ore. A nozzle carrying high-pressure water and mounted upon a rigid swivel can be turned on and directed by the operator to any crevice in the upturned car bottom where the ore has not been dislodged. The quantity of water used is so small that it is insignificant in the ore. The ore falling from the car passes over grids that hold back any large lumps and then drops into a bin. There are gates

FIG. 12—20. Car dumper discharging iron ore from a railroad car into a transfer car.

FIG. 12-21. View of an ore yard serving the blast furnaces in the background.

at the bottom of this bin which are operated by the transfer-car operator in filling the transfer car. A few dumpers have been built which are movable, in that they are able to move to any location and dump the ore directly into the ore trough. These dumpers, however, must be attended by a locomotive when operating; consequently, only one car can be spotted on the dumper at a time. Preference seems to be for the stationary dumper with transfer cars. One type of car dumper is shown in Figure 12-20.

Ore Yard and Ore Bridges—The ore yard (Figure 12-21) is a large space, sometimes with concrete bottom and sides, which parallels the furnace bin structure and serves as storage for approximately a half-year's consumption of ore. Its width is determined by the practical maximum span of the ore bridge, which for a bridge supported at each end amounts to about 350 feet. Other types of bridges are supported by two legs which run longitudinally through the ore yard (dividing the yard into three separate piles); such bridges have cantilevers on the outer sides of the two supporting legs. This type gives a longer trolley travel but does not necessarily store any more ore per running foot because of the space occupied by the supporting structures. A trolley running on the bridge proper carries a grab bucket of about 15 tons capacity which, when stocking, lifts the ore from the dumping trough and distributes it on the pile, or removes the ore from the pile and deposits it either directly into the bins or into a bin or transfer car (Figure 12-22) which in turn distributes the ore. Some bridges are provided with a bin hanging from the bridge into which the bucket dumps permitting the bridge to keep working while the bin car is dumping its load. In order to obtain the maximum

benefit of mixing, the ore is stocked in horizontal layers and removed in vertical slices. For this reason, the use of ore direct from hopper cars unloaded from the trestle into the bins is undesirable. The details of the ore-handling system will vary considerably but the general scheme is essentially as stated.

Trestle and Stockhouse—If it were not for the fact that all parts of a blast-furnace plant are essential to its operation, the stockhouse might be considered as the most important unit of the plant, with the exception of the furnace itself, since its function is to deliver to the furnace the correct quantities of ore, fuel and flux without which the furnace cannot operate.

The constructional details of the trestle differ considerably but a trestle of modern design consists of a reinforced concrete wall on the stock yard side and steel columns on the furnace side, between which is a crosswork of transverse and longitudinal girders. On top, these girders support three or four railroad tracks, and on the bottom, the bins proper. The track nearest the stock yard carries a side-dump bin car, the next track carries railroad cars containing materials such as limestone, dolomite, scale, scrap, etc., which are unloaded by hand, and the next one or two tracks carry coke cars. When there are more than six furnaces in a line, it is desirable to have two coke tracks so that the coke cars, not fully unloaded, may be by-passed. Where the coke bins are filled by a belt conveyer, one coke track for emergency use is sufficient. This construction results in two lines of bins in the stockhouse, one line containing ore, flux and miscellaneous materials and the other containing coke.

A scale car, equipped with scales to weigh accurately each material drawn, runs underneath the first line of

FIG. 12-22. Transfer or bin car emptying ore into stock-house pocket.

bins. The car may have a capacity of up to 40 tons and carries two pockets. The ore and miscellaneous material bins are equipped with gates on the bottom which may be operated either mechanically or by hand (Figure 12-23). The car delivers its load by discharging into chutes leading to the skips. Underneath the second row of coke bins, a belt conveyor, fed by vibrating feeders at each coke bin, runs toward the skip pit while another conveyor on the other side of the skip pit performs the same function for the coke bins on that side. Each conveyor discharges upon a vibrating screen where the coke fines are screened out and the oversize discharged into a weigh hopper. Here the coke is weighed and at a pre-

determined weight an electrical contact stops the belt and vibrating coke feeders. Provision also is made usually to stop the belt and feeders in case a predetermined volume, rather than weight, is desired. From the weigh hoppers, the coke is discharged directly into the skips. Considerable time is saved by this method, as the operator can be drawing ore while the coke loading is being taken care of automatically. The undersized coke from the vibrating screen is removed by a small bucket hoist, or by conveyor belt, to a storage bin where it is rescreened into coarse and fine. The coarse may be recharged separately into the furnace or may be sold as domestic coke, while the fines are used under boilers,

FIG. 12-23. Scale car in stockhouse, showing overhead ore bin gates from which car is filled, and chutes that carry coke from bins directly to skips.

FIG. 12—24. Instruments assist the furnaceman by automatically indicating, recording and controlling temperatures, pressures, flows, etc., at the important points in the blast-furnace system indicated in this schematic representation of a blast furnace and its auxiliaries.

as fuel in the sintering processes, and to make up the bottom of soaking pits. In the bucket hoist the same scheme as that just described is used for the ore, flux and miscellaneous materials, but the bucket itself is placed, on descending, upon a revolving cone which keeps the bucket revolving during the time it is receiving the charge. A **charge**, or **round**, is that minimum combination of skip or bucket loads of material which together provide the balanced complement necessary to produce hot metal of the desired specification. Normally, the entire charge is deposited on the large bell by successive skips or buckets and enters the furnace upon lowering of the bell. However, through preference or because of the limited capacity of the large bell hopper, the charge or round may be "split" and require two drops of the large bell.

Blowers, Boilers, Pump Houses, Etc.—These vital parts of the blast-furnace equipment present features of more interest to engineers than to metallurgists. The blowing of the furnace, on all later installations, is by turbo blower, this type of equipment having almost com-

pletely displaced internal-combustion gas engines and steam reciprocating engines. It is noted that many installations now receive steam at 700 pounds per square inch pressure with a total temperature of 750°F. There has been at least one installation abroad where a gas turbine has been used to blow a blast furnace. The boilers almost universally burn secondary clean gas, with unit coal pulverizers provided at each boiler for auxiliary firing. The water system is usually designed to deliver water at tuyere level at 30 pounds per square inch head. The water is treated with lime if it is of a corrosive nature, and may be chlorinated sufficiently to prevent algae growth.

Instrumentation and Control—The blast-furnace operator is aided and guided in establishing and maintaining the best possible balance between the many variable factors affecting furnace operation by numerous automatic devices which indicate or record conditions at various points in the furnace system (Figure 12—24) and may operate control mechanisms that automatically regulate important variables.

SECTION 5

OPERATION OF THE FURNACE

When a blast furnace is completed and provided with as much of the equipment described above as is necessary or desired, the active campaign to produce iron may begin. In blast-furnace parlance, the process of

starting a furnace is called **blowing in**. It is carried out in three steps, drying, filling, and lighting.

Drying—Newly constructed furnaces and stoves, or new linings, must be carefully and thoroughly dried

before they are put into service. In the case of the blast furnace, any one of several methods may be employed. In one method the drying is accomplished by a gas fire in the hearth but this method has become obsolete because of some hazards involved. Another and safe method is to build three or four "Dutch ovens" at different points outside of the hearth, fire these ovens with coal or coke, or a combination of the two, and allow the products of combustion to be drawn through the cooler openings into the bottom of the furnace. This method requires the assembling of the fuel at the Dutch ovens and the disposal of the ashes. A third method makes use of the hot blast for drying. In carrying out this method, the stoves are heated as when the furnace is operating, and air from the blowers is passed through the stoves, then to the bottom of the furnace through the regular connections and a number of special pipes extending from the tuyeres inside the furnace to the bottom. While this method also is perfectly safe, it can be used only where gas is available for heating the stoves, and is not practicable when the drying must be extended over long periods of time. Still another safe method is to build a fire of scrap lumber in the hearth of the furnace. The fire may be kept burning for several weeks. During the drying out, the openings at the bottom of the furnace are kept covered to prevent the drawing in of an excessive amount of air, while the bleeders at the top are kept open. In all cases, the heat must be applied very gradually. About ten days are required with these methods, but when feasible to do so, this time well may be prolonged to two weeks or more. Since the mass of brickwork in the hearth is quite large, it is customary to dry this part of the furnace as each course of bottom block is being laid. This is accomplished by placing unit heaters or knock-down salamanders on top of the newly laid course during the off turn. Some operators employ thin electric heating strips between the lower two courses of bottom blocks and dry by electricity. In some cases, steam is turned into the cooling staves to help the drying. Following the drying period, some heat must be kept up until such time as the furnace is put on blast to prevent absorption of moisture from the atmosphere. Small unit heaters at the iron notch and cinder notch have worked quite successfully in accomplishing this objective.

Filling—After the furnace is sufficiently dried, it is allowed to cool slightly, and then the important process of filling is begun. While different individuals pursue slightly different methods, the general scheme is carried out rather uniformly. Briefly stated, it consists of first placing wood and coke, or coke alone, on the bottom to a height somewhat below the level of the tuyeres, about which any easily ignited material, preferably charcoal, is piled; then following this material with a large quantity of coke, mixed with enough limestone to flux its ash, and gradually introducing ore with the proper amount of flux. Good practice requires that this initial volume of coke should be about half the cubical contents of the furnace. Sometimes, to get an easily fusible slag and a good volume of it, blast-furnace slag may be introduced ahead of the ore. These are called **blow-in burdens**, and additions are made until the furnace has been filled to the stock line, when it is ready for lighting.

Lighting—The lighting of the materials in the bottom of the furnace may be done in several ways. If the space in front of the tuyeres has been filled with light kindling wood, oil is poured or sprayed in at the tuyeres until the wood is thoroughly soaked with it. Then, with the furnace isolated from the gas-main system beyond the dustcatcher, mains and bells closed, the bleeder and ex-

plosion doors are opened, a light blast is turned on, and the wood ignited. Often, a wood fire is built in the stove nearest the furnace, and the oil-soaked wood is ignited by blowing sparks over with the blast. Others prefer to light the furnace with hot blast alone or with an oxygen lance. With a light blast on, the wood soon burns away, and the stock begins to settle, after which the blast volume is gradually increased. Some furnacemen start off, after the fires are well caught, with a fairly high blast volume for a few minutes, in order to drive the flames well in toward the center of the furnace and consume the wood quickly, as it is thought that a better initial settling of the stock is thus obtained. As soon as the stock gives signs of settling, the blast volume is reduced to that normally used for the rest of the blowing-in period, which volume is at first about $\frac{1}{4}$ that used when the furnace is in full blast. Up to this point a great deal of gas and smoke escapes from the furnace openings, and great care must be exercised, for the gases contain a high percentage of carbon monoxide. Great care is also required to prevent explosions, because, as pointed out in the chapter on fuels, mixtures of furnace gas and air in a wide range of proportions are explosive. Also, the gas from a newly lighted furnace contains hydrogen above that normally present. Since the interstices of the stock in the furnace are filled with air at first, an explosive mixture may be formed any time soon after the lighting, and if this mixture should be ignited it might cause serious damage. The difficulty is overcome generally by allowing the gas to escape through the bleeders to the atmosphere for several hours, after which time valves to the gas-main system are opened. Outlets at the ends of the gas mains are kept open until all the air has been expelled, which condition is indicated by the color and odor of the escaping gas. Both men and fires are kept away from these openings until the outlets have been closed.

Heating the Bottom—Another feature connected with the lighting of the furnace is heating up the bottom, which is warmed by the drying-out fires to only a slight degree as compared with the temperature required to keep molten the slag and iron that form. In order to have the bottom at the proper temperature when slag begins to form, two methods are employed, both of which involve leaving an opening at the tapping hole so as to draw flame downward from the tuyeres upon the bottom. In the first method, a round tapered wood plug, three or four inches in diameter at the smaller end, is placed in the taphole and the space about it is packed full and tight with clay. With the rise in temperature due to the burning of the wood and coke in the bottom, the clay sets, and this plug is then removed, which permits the flame from within to shoot forth, thus heating up the runner outside as well as the bottom inside the furnace. When slag begins to flow from the taphole, the opening is closed until time for tapping the first iron has arrived. In the second method, an iron pipe, about four inches in diameter, is placed in the furnace before it is filled, so that one end protrudes from the taphole outside the hearth, while the other extends to the center of the furnace. The space about the pipe where it passes through the wall of the hearth is tamped with clay or ball stuff, which is also built up about the part of the pipe within the furnace for a foot or so from the hearth wall. When the furnace is lighted, the gas flame is drawn to the center of the bottom to pour forth from the exterior end of the pipe. This pipe need not be moved until a fairly large flow of slag is attained, when it is drawn from the taphole, which is immediately closed, as in the case of the wooden plug.

Heating the Stoves—The temperature of the hot blast when the furnace is in full operation is about 1000°F (540°C) and it is a great help if the stoves can be heated to provide this temperature at the time of lighting of furnace, for the furnace and filling are cold to the bottom. The required stove temperature usually is obtained by the use of blast furnace gas, but in the case of isolated furnaces where gas is not available before starting up the furnace, the stoves are heated as hot as possible by wood and coal fires, by natural gas, or by special fuel-oil burners before lighting the furnace.

Blast Control—For a good blow-in it is now regarded that the volume of blast blown should be increased fairly rapidly (as opposed to former practice requiring as much as a month to get to full wind). Rapid increase in the blast produces better penetration at the tuyeres; the furnace more quickly starts to work regularly. An empirical figure of about 125 cubic feet of blast per minute per square inch of tuyere area seems to produce the desired penetration. The usual procedure is to light the furnace with at least half of the tuyeres plugged and then to open a tuyere at a time as the blast is increased. In addition, many operators use a tuyere smaller in diameter when blowing-in than those which will be used when the furnace reaches normal operation. The furnace is lighted with both the "snorter" (snort valve) and peep sights open which gives hardly more than a breeze entering the furnace. The peep sights are closed gradually and then the snorter also is closed gradually so that 4 or 5 hours after the furnace has been lighted, the snorter is completely closed. The divergence in opinion as to how fast the blast should be increased is indicated in the following tabulation of two blow-ins.

Per Cent of Full Wind Being Blown	Hours from Time Snort Valve is Closed	
	Operation A	Operation B
25.0		Start
40.0	Start	12.0
50.0	4.0	20.0
60.0	9.0	28.0
70.0	19.0	36.0
80.0	34.0	48.0
90.0	54.0	72.0

In both operations it requires several days to get the last ten per cent of the wind on the furnace. The economic importance of obtaining production from such a costly assembly of equipment is obvious.

Flushing and Casting—About 18 hours after the snorter has been closed, there will be a sufficient accumulation of slag to flush. This is done by removing the bott from the monkey, and pricking through the solid slag with a steel bar. The bleeder is closed several hours after the snorter is closed and the gas now can be used in the stoves and boilers. Up to this time the blow-in blast-furnace gas is higher in carbon monoxide and hydrogen than normal, with generally unsatisfactory combustion characteristics. With a multiple furnace plant, the procedure is to turn the steam off the dustcatcher and open the water seal or goggle valve between the dustcatcher and the gas line, thus permitting the gas from the other furnaces to flow momentarily through the open bleeder, after which the bleeder is closed. In a single furnace plant, a connection such as a boiler burner is left open at the extreme end of the gas main and the gas forces the air ahead of it through the open connection. Extreme care must be exercised at this point that no fires are adjacent to the open connection which might ignite the explosive mixture being forced out of the connection.

It requires about 24 to 30 hours before enough iron accumulates for the first cast. A hole is bored by means of a long auger or drill, electrically or pneumatically operated, into the clay plug of the tapping hole until the hard iron skull is reached. The loose dust is blown out of the hole by a jet of compressed air. The **splasher** having been put in place, the opening of the hole is completed by an oxygen lance, a small quantity of coal having previously been placed into the end of the hole to provide a means of "lighting the lance." The coal itself is ignited from the heat of the red hot skull, and soon the iron skull is melted. The iron then flows down the runner, under the skimmer, and into the ladles provided to receive it. During the flow of the metal, samples of the iron for chemical analysis and fracture tests are taken by collecting small spoonfuls from the main runner. The iron is usually analyzed for silicon, sulphur, manganese, and phosphorus. The slag which follows the iron near the end of the cast is stopped by the skimmer where it is run off through a runner to the slag ladles or granulating pit. When the iron has almost ceased to flow and gases are pouring from the hole, the blower signals the blowing room to reduce the blast and also may open the snort valve, it being the practice with modern guns to stop the hole with about 10 pounds blast pressure on the furnace. The clay gun is then swung into position for stopping the hole and the clay forced into the tap hole.

Care of Runners—After the tapping hole has been closed (from one to three minutes being required), the troughs are emptied, and preparations for the next cast are begun. The runners are cleaned carefully of both metal and slag, and their inside surfaces are carefully brushed with a thick clay or loam slurry, which, when dry, protects the trough, and prevents the iron from sticking to the runner. More recently a preference has been shown for a carbon-lined main trough due to the reduced scrap produced, since the iron does not stick to the carbon brick. For such main runners a steel plate trough is built, lined next to the plate with firebrick, and a carbon-brick facing placed next to the firebrick. The carbon brick is plastered with clay before cast time in order to keep the carbon from oxidizing during cast. Water can be turned directly on the red-hot carbon after a cast without any deleterious effects.

Sampling the Iron—Sampling pig iron is a very important part of every tapping (cast). As the iron is graded by chemical composition, care must be taken to obtain a sample that will be representative of the whole cast. This sample, therefore, is generally made up of a number of equal portions taken from the main runner at the farther side of the skimmer and at periods corresponding to the first, middle, and last thirds of the cast. These samples consist of small castings made by pouring the metal into a mold. Chill tests of all slags are also taken and a daily composite analysis made for each furnace.

Changing Stoves—The temperature of a furnace at the hearth is a matter of great importance, as this is one of the two main factors which control the quality of the iron produced. The other main factor is the composition of the slag. One of the means of regulating hearth temperature is by control of the hot-blast temperature. This may be raised or lowered by use of the mixer valve, and can be kept high by proper manipulation of the stoves. It has been said with some justice that when the slag is of proper composition and temperature, the quality of the iron automatically will take care of itself. As a part of the routine of blast-furnace work, the tending of stoves is of importance. They must be kept clean and be changed regularly and at not too long intervals.

SECTION 6

CHEMISTRY OF THE PROCESS

The reactions of the blast furnace have been thoroughly investigated, not only by deductions from observation and controlled laboratory experiments, but also by experiments conducted with small experimental furnaces and indeed with full size furnaces—the latter being conducted through holes left in the wall when the furnace was built. To summarize the knowledge thus gained in the briefest possible form, the several possible reactions for each element entering the furnace are set down. At one zone or another each may occur, though the final result is the same regardless of the precise stages actually passed through by any particular part of the charge.

Reactions of Oxygen and Carbon—20.8 per cent of the blast by volume or 23.2 per cent by weight is oxygen, which enters the furnace at a high temperature, say 1000°F (540°C) and, coming in contact with hot coke, immediately reacts with carbon, giving off heat, thus:

In the presence of an excess of carbon at a high temperature, CO_2 is at once reduced to CO, and 73390 Btu are absorbed per pound-molecule of CO_2 .

The net heat, then, from (1) and (2) is 170010 - 73390 = 96620 Btu, or 48310 Btu per pound mol. of CO.

At moderately high temperatures the CO gas acts upon ferric oxide as a reducing agent and in so doing will liberate heat at the same time, thus:

At temperatures ranging from 482°F to 1292°F (250 to 700°C), the latter a dull red heat, the reduction of Fe_2O_3 by CO may take place in three steps, the Fe_2O_3 being successively reduced to Fe_3O_4 , FeO, and finally to Fe. That the reduction of the ore in the blast furnace does take place in this way is suggested by the fact that a large part (60 to 74 per cent) of the flue dust ejected from the top of the furnace is magnetic though only Fe_3O_4 may have been charged. If all three of these reactions proceed to completion, the total heat liberated and the total iron reduced would be the same as that in reaction (3) for equal weights of CO. A very interesting reaction may take place between Fe_3O_4 and CO at low temperature as in Reaction (4), in which carbon is deposited and heat is liberated, thus:

* In the interests of uniformity, all heats of formation used in this book, unless otherwise stated, are expressed in Btu per pound-molecule at 64.4° F (18° C), based on the values given in "The Thermo-chemistry of the Chemical Substances," by F. Russell Bichowski and Frederick D. Rossini, Reinhold Publishing Corp., New York (1936). It is, however, recognized that the heating value of coke carbon is higher than that given for carbon in the graphitic form; for coke carbon the value is 174,600 Btu per pound mol., or 14,550 Btu per pound of coke carbon.

Carbon is not deposited by the action of CO upon FeO or Fe_3O_4 (magnetite), but it may be deposited at temperatures below 1112°F (600°C) by the action of metallic iron upon CO, thus: $Fe + CO = FeO + C$. Also, as the ore is reduced, carbon may be deposited by the reversible reaction,

Since this is an equilibrium reaction, the amount of carbon deposited depends upon the ratio of CO to CO_2 and the temperature, reaching a maximum at about 942°F (505°C) with the ratio $CO/CO_2 = 0.4$. This free carbon penetrates a porous ore to some extent, and seemingly becomes a more powerful deoxidizer of the ore than CO at temperatures above 1382°F (750°C).

The CO_2 formed in the preceding reactions and from the decomposition of limestone may act as an oxidizing agent, absorbing or giving off heat, as shown in Reactions (5), (6) and (7).

These reactions may take place at temperatures ranging from about 662° to 1562°F (350° to 740°C) and to a degree are governed by the relative amounts of CO_2 and CO in the furnace gas.

Carbon alone is also a reducing agent toward oxides of iron at temperatures of 942° to 1292°F (505° to 700°C) but the reduction of ore by carbon alone absorbs much heat whether the reduction takes place at these or at higher temperatures, as shown by Reactions (8), (9) and (10). However, the carbon monoxide produced can be utilized in the indirect reduction of more iron oxide and thus liberate heat, minimizing the net heat-absorbing effect.

Under proper conditions the reduction of Fe_3O_4 by solid carbon may take place in a direct way, thus:

At very high temperatures—say around 2700°F—carbon in large excess may reduce manganese, silicon, and phosphorus oxides, the reactions being represented thus:

Since it is probable that silica often does not exist as such, but rather in chemical combination with other oxides, and since the silicon is dissolved in iron, equation (13) cannot be used as absolute in determining the heat absorbed.

Some oxygen also enters the furnace as water vapor in the blast, where the following endothermic reaction occurs:

The hydrogen formed may do work temporarily by reacting with iron oxide and reducing it thus:

The water so formed is again decomposed as shown by the presence of hydrogen in blast-furnace gas. Therefore, the net energy result from water vapor is a loss.

In this connection it should be noticed that, since carbon is the only fuel employed, the carbon-oxygen reactions must be relied upon to furnish the heat required in the process, and that only a few of these are heat producing. The net heat from Reactions (1) and (2) and the heat evolved by Reactions (3) and (4) produce most of the heat absorbed by other modes of reduction, also that required to dry the raw materials, to decompose the carbonates and hygroscopic minerals, to melt the iron and slag, and to replace the heat wasted. On this account they are among the most important reactions occurring in the furnace.

Behavior of Nitrogen—Nitrogen and the other inert gases of the air, totaling 79.2 per cent of the blast by volume, pass through the furnace, for the most part, unchanged chemically. Since they equal in weight about six-tenths of all the other materials entering the furnace, they play an important part in heat convection, and make a source of unavoidable heat waste. Some nitrogen, however, possibly may react with alkali carbonates and carbon to form salts of hydrocyanic acid.

This reaction explains the trace of cyanogen (CN), analytically detectable in blast-furnace gases. In the iron blast furnace the cyanide compounds are largely decomposed or oxidized within a short distance above the bosh, and in furnaces making ferroalloys, the gas is likely to contain more cyanogen, perhaps because the zone of cyanide decomposition is nearer the top.

Carbon in Pig Iron—Other than the metal iron itself, carbon is the most important element in pig iron. In iron for steelmaking, since the carbon must be removed largely by oxidation, it may be said to be a fuel. Due to the nature of the process and the chemical properties of the elements involved the amount of carbon in pig iron cannot be controlled wholly in the blast furnace except, indeed, within a relatively narrow range above a certain minimum which varies for different grades. The reasons for this statement may be explained briefly

as follows: in the blast furnace, the ore is reduced largely in the upper part of the furnace, and the reduced iron is melted in the fusion zone above the tuyeres, whence it falls in drops through the slag into the hearth where it lies in contact with the bottom of the central column of coke. In the hearth, the iron gives up sulphur to the slag, the sulphur contents of the metal and slag finally approaching a condition of equilibrium. The amount of carbon absorbed depends not only upon the temperature, but also upon the percentages of manganese, silicon and phosphorus which the iron contains; for example, high temperature and high-manganese content increase the carbon content of the iron.

Briefly, the factors affecting the total carbon in pig iron are as follows:

1. *Hearth temperature.* At 2100°F (1150°C), under favorable conditions, the purest iron will absorb 4.25 per cent carbon, and this carbon content is increased by about 0.15 per cent for each increase of 100°F (55°C). Hearth temperatures, however, are adjusted to other more important factors, such as the control of silicon and sulphur. In considering the effect of temperature upon molten iron, it is necessary to keep in mind that the effective temperatures are inevitably above a certain minimum of about 2085°F (1140°C), marking the freezing point of the iron-carbon eutectic (see discussion of the iron-carbon equilibrium diagram in Chapter 42).
2. *Rate of cooling immediately after tapping.* Control of the cooling rate of the liquid iron gives the only chance of controlling the total carbon. If the cooling prior to solidification is slow, carbon in excess of the eutectic composition separates as graphite, which rises to help form the mixture of graphite and slag known as kish. Such control of carbon is restricted by other factors.
3. *Composition of the iron.* The proportion of carbon in the eutectic alloy and the total amount of carbon the iron will absorb at a given temperature are affected by the presence of other elements, the individual effects of different elements being about as follows:
 - (a) *Silicon* reduces progressively the carbon in the eutectic from 4.25 per cent to about 3.50 per cent with 3.0 per cent silicon present, but as a high temperature (at which carbon solubility is increased) is necessary to obtain the higher silicon, the total carbon may not be much affected, the net result being rather to decrease the combined carbon and increase the graphitic. Since low silicon is obtained at low temperature, lowering the silicon will neither raise nor lower the carbon much from about 4.25 per cent.
 - (b) *Phosphorus* decreases the total carbon the iron will absorb, one per cent causing a drop of about 0.3 per cent in the carbon held at any temperature above 2200°F (1205°C). It probably lowers the melting point of the eutectic, hence increases the loss of carbon as kish when the iron is held a time in the liquid state.
 - (c) *Manganese*, also *chromium*, *titanium*, *vanadium*, *tungsten*, and *columbium* are carbide-forming elements and tend to increase the total carbon and to hold more of it in combined form on cooling. The effect of manganese in increasing the carbon is much less than the

effect of silicon in decreasing the carbon, one per cent manganese increasing the total carbon by about 0.04 per cent, and one per cent silicon decreasing it by about 0.3 per cent. Thus, an increase of 7 to 9 per cent manganese would be required to neutralize the effect of a one per cent increase in the silicon content.

- (d) **Sulphur**, in amounts usually occurring in pig iron (0.03 to 0.05 per cent), even up to 0.2 per cent, has little effect upon the total carbon. It does, however, show a marked effect in opposing the formation of graphite, so that with silicon constant, say at one per cent, a chill test reveals any increase in sulphur by increasing the depth of chill.

Silicon—Silicon enters the furnace as silica (SiO_2), some of which may be combined with bases as silicates. At temperatures of about 2192°F (1200°C), corresponding to the fusion zone in the blast furnace, the greater portion of this silica combines with lime, CaO , and other bases to form silicates. However, at a high temperature, such as exists in the hearth of the furnace and in the presence of carbon, silica is reduced, and the resultant silicon combines with the iron to form iron silicide, as represented by the following two equations:

The ordinary amounts of silicon dissolve in the iron and formation of the silicide is theoretical. Besides the effects of silicon upon the carbon given above, other uses and characteristics are listed as follows:

1. In steelmaking processes, it is oxidized to SiO_2 and enters the slag. This reaction is important in the acid Bessemer process (and to a less degree in other processes) because it is an essential source of heat.
2. In the blast furnace, the amount reduced, though difficult to control closely, depends upon the slag composition and the temperature. Below 2700°F silicon may absorb oxygen from carbon monoxide (CO) and its reduction absorbs much heat; hence, high temperature and the presence of iron with which it can combine instantly are essential. Its reduction, therefore, is possible only below the melting zone.

Manganese—Coming now to the elements that are introduced into the pig iron through reduction processes occurring in the furnace, manganese is the one most closely resembling iron in its chemical conduct. While traces of the element are found in both the limestone and the coke ash, practically all that entering the furnace is present as an ingredient of the ore or in materials such as open-hearth slag or converter slag, in which it occurs as oxide, silicate or phosphate. The manganese compounds are never wholly reduced in the furnace, and the proportion of them that is so reduced depends upon the conditions of the temperature and basicity of the slag. Under conditions ordinarily prevailing in the blast furnace producing pig iron, from 50 to 75 per cent of the total amount of this element charged will be found in the pig iron, the highest proportion being obtained with high hearth temperatures and basic slags.

Manganese alloys with iron in all proportions. An alloy containing 10 to 25 per cent manganese is called *spiegel*, or *spiegeleisen*. Alloys containing 40 to 80 per cent manganese are called *ferromanganese*.

Manganese decreases the effects of sulphur, with

which it combines, forming MnS and replacing iron in the sulphide FeS . If a high-manganese iron is kept molten for some time, some of the sulphur it contains will react with manganese in the iron to form manganese sulphide, which will rise to the surface, like slag, and react with the oxygen of air, liberating sulphur as oxides. With high-manganese ores, this fact can be utilized to reduce the sulphur content of the pig iron, but in order thus to obtain a material reduction of the sulphur content the manganese content of the pig iron should exceed 2 per cent. For these reasons, a high content of manganese is desirable in some irons for the foundry and in all irons in open-hearth steelmaking purposes. Manganese is less desirable in iron to be utilized in the Bessemer process in which it is oxidized and unites with silica to form a slag that fuses at a comparatively low temperature and is very fluid, so that iron containing more than 0.5 per cent manganese gives rise to a condition known as a "sloppy" heat when blowing iron in the Bessemer converter. High manganese is also undesirable in certain grades of foundry iron. Hence, the manufacture of merchant iron requires that manganese, as well as silicon, sulphur, and phosphorus, be controlled.

Phosphorus—Phosphorus is the only element entering the blast furnace over which the skill of the furnaceman has practically no control, except by proper selection of raw materials. Its compounds are completely reduced, so that essentially all the phosphorus in the raw materials is found in the metal. Phosphorus enters the furnace with the charge in the form of phosphates. At very high temperatures and in the presence of carbon, these compounds are reduced, as shown in Reaction (14). Phosphorus may react with iron to form iron phosphide, thus:

This phosphide, however, is soluble in iron and becomes a part of the metallic bath in the blast furnace.

Disposition of Sulphur—Sulphur is carried into the furnace mainly by the coke, though 10 to 20 per cent of the total is often found in the ore and the limestone. The sulphur contained in the coke enters in the form of elementary sulphur and FeS , all of which, when melted, alloy with the iron in the furnace; a smaller portion, in the form of sulphates, such as CaSO_4 , enters as an impurity in the ore, limestone, and coke, and is reduced to sulphide in the presence of carbon. At a very high temperature and in the presence of carbon and a basic slag (wherein the ratio of $\text{CaO} + \text{MgO}$ to $\text{SiO}_2 + \text{Al}_2\text{O}_3$ is greater than 1), a reaction takes place which is usually represented as follows:

This reaction, being influenced by other conditions as well as those just mentioned, never goes to completion, so a small portion of the sulphur remains in combination with the iron. This iron sulphide is soluble in iron, hence, becomes a part of the metal.

The blast furnace provides the only economically positive means for the control of sulphur. Removal of sulphur in any of the steelmaking processes is either uncertain or expensive, or both. For this reason, pig iron containing less than 0.05 per cent sulphur is preferable for making steel by all the fusion processes.

Action of Calcium and Magnesium—Calcium and magnesium enter the furnace mostly as carbonates. Small portions may be in the form of silicates, in which CaO and MgO are combined with SiO_2 , and may undergo no chemical change in the furnace. The carbonates, however, are slowly decomposed at temperatures above

1470°F (800°C), liberating CO₂, with the reaction becoming rapid at 1740°F (950°C).

At the proper temperature for their formation the caustic lime and magnesia, in intimate contact with SiO₂, both combine with it to form slags.

Action of Aluminum—Aluminum, in the form of alumina (Al₂O₃) and aluminum silicates, are found in ore, flux, and fuel. Neither alumina nor aluminum silicates are reduced under the conditions that prevail in a blast furnace. Alumina may exert a marked influence upon the fluidity and fusibility of the slag, and increases the desulphurizing power of the slag. Alumina in slag is neither definitely acid nor basic. Investigating the question as to whether or not alumina is an acid or a base, runs of one week each were made in which the alumina in the slag was varied from 11 per cent to 21 per cent, approximately, to produce the same grade of pig iron. The data were then collected and compared as shown in the tabulation below. It will be noticed that magnesia has been omitted. This omission was made because the magnesia in the slag was fairly constant in all cases, ranging between 2.1 and 2.4 per cent.

Furnace	1	2	3	4	5	6
	Al ₂ O ₃	SiO ₂	CaO	CaO	CaO + Al ₂ O ₃	CaO
	%	%	%	Al ₂ O ₃ + SiO ₂	SiO ₂	SiO ₂
A	11.5	34.5	51.5	1.20	1.82	1.49
A	18.6	31.2	47.9	0.96	2.13	1.53
G	20.1	31.0	46.5	0.91	2.15	1.50
F	20.8	30.4	46.5	0.91	2.21	1.53

Columns 4, 5, and 6 give the acid-to-base ratios with the alumina considered respectively as an acid, a base, and a neutral or amphoteric component respectively. It is at once noticed that with alumina omitted, the ratios are almost constant as they should be to produce iron of the same kind, grade, and quality. The ratios in columns 4 and 5 show a variation not to be expected under the conditions of the experiment. A comparison of columns 1, 2, and 3 indicates alumina may act as an amphoteric component. Many furnaces are running with higher magnesia (about 5 per cent) in the slag than that indicated above and a ratio of lime-plus-magnesia to silica of from 1.35 to 1.40 is considered as producing an ideal slag.

Action of Less Abundant Elements—Titanium, potassium, sodium, zinc, arsenic, barium, beryllium, boron, copper, chromium, nickel, selenium, tellurium, tin, zirconium, and vanadium are some other elements which are present in very small, but varying, amounts in the raw materials going to the blast furnace.

Titanium enters the furnace as titania, TiO₂, combined with some base, or as ilmenite (FeTiO₃ or FeO·TiO₂). When titania comprises less than about two per cent of the ore burden, 50 to 60 per cent of the titania will appear in the slag as TiO₂, and the balance will be reduced and appear in the iron. When TiO₂ in the slag exceeds

about 1.5 per cent, slags may be very viscous and result in irregular furnace operation. Also, the character of the hot metal may be adversely affected, resulting in excessive skulling of hot-metal ladles. Under the conditions prevailing in the furnace, titanium exhibits a slight tendency to combine with carbon and nitrogen to form titanium cyano-nitride. This substance is sometimes found in the salamander on the hearths of furnaces being repaired. Here, it occurs in the form of small cubes that have the appearance of copper.

Beryllium and **zirconium** are similar to titanium, but much more difficult to reduce, so that they probably pass through unchanged.

The **alkalies**, soda and potash, are found in nearly all blast-furnace slags; when they are present in the raw materials to a considerable extent, they may, however, flux the furnace lining, and in part be volatilized to escape with the gases from which they later may condense to form troublesome accretions (scaffolds) on the furnace lining. They may play a part in the furnace reactions, for it is known that Na₂CO₃ and K₂CO₃ accelerate somewhat the reduction of Fe₂O₃ at 1650°F (900°C).

Zinc is a very troublesome element when present in blast-furnace material. Its compounds may be reduced in the lower regions of the stack; and, if so, the zinc is volatilized, driven upward and oxidizes to zinc oxide, which condenses on the walls of the colder part of the flues and in time closes up small passages to such an extent that the flow of the gases is restricted seriously. Zinc oxide also tends to combine with the alumina in the firebrick lining of the furnace, causing the brick to expand with damaging results.

Arsenic acts very much like phosphorus. Its compounds are reduced, and the resultant elementary arsenic then combines with iron to form iron arsenide, which dissolves in the metal.

Barium is similar to calcium, acting as a nonreducible basic flux; in an ore, it may be present as the carbonate, silicate, or sulphate. BaO is a base similar to CaO, but of higher molecular weight, hence does not increase basicity on a percentage basis, nor the desulphurizing power, as rapidly as CaO by almost one-third. On a molar basis its effect is similar to CaO.

The compounds of **boron** presumably behave as a flux.

Copper compounds are readily reduced yielding metallic copper, which alloys with the iron.

Chromium is reduced from its oxides with difficulty in the blast furnace, an exceedingly high temperature and an acid slag being most favorable for the reduction of its oxides. Small amounts appear to be more nearly completely reduced than large amounts.

Compounds of **nickel** and **vanadium** are almost completely reduced, the resulting nickel and vanadium alloying with the iron.

Tin is rare in raw materials of the United States; if introduced, its compounds are reduced and the tin alloys with the iron.

Selenium and **tellurium**, though somewhat rare, may be present in some raw materials; in their reactions, they are somewhat similar to sulphur but with an even greater tendency to remain with the metal.

Reactions Within the Furnace—With all the foregoing facts concerning the properties of the various ingredients of the raw materials in mind, the changes that take place in the blast furnace are understood more easily. The accompanying chart (Figure 12—25) gives a graphic representation of these changes, showing the relative weights and volumes of materials, the reactions and the temperatures at which the changes take place, and the

FIG. 12-25. The making of a ton of pig iron, indicating the raw materials used, the products, and their relative weights, and the reactions that take place at various levels in the blast furnace. NOTE: Shape of the furnace has been distorted greatly to accommodate notations.

final disposition of the products. In studying this chart, however, one important fact should be kept in mind. It is this: Owing to the conditions prevailing within the furnace, very few, if any, of the reactions will be complete, that is, use up all the material at hand at the location indicated. Thus, the first reaction, showing the reduction of the ore to metallic iron with the deposition of carbon, affects only a part of the ore and gas. This condition, with but one exception, holds for all these reactions. Even limestone, which will decompose completely into lime and carbon dioxide at 1800°F if given sufficient time, will often reach the tuyeres in some small part as calcium carbonate. The fact that iron and manganese oxides are not completely reduced is established by their presence in the slag. The one exception to this rule is phosphorus. Its compounds, down to small traces, seemingly are reduced completely.

The explanation for these statements is to be found only in a careful study of chemical laws in connection with the conditions prevailing in the furnace. Such a study reveals the fact that the reactions in the upper part of the stack of the furnace are subject to conflicting tendencies. Thus, the gaseous substances, CO and CO₂, are in constant contact with the solid substances, Fe₂O₃, FeO, and C. Of these, Fe₂O₃ and CO₂ are oxidizing agents. FeO and CO may act as either oxidizing or reducing agents, while C and Fe are reducing agents. With these substances in contact at any given temperature and in any given proportions, the reversible reactions would tend to proceed in a given direction until equilibrium should be established, and no further change would occur until either the concentration of one of the reacting substances or the temperature changes. Then the reactions would once more proceed in a direction that would again establish equilibrium. But the slow downward movement of the stock to regions of higher and higher temperatures, the presence of an excess of carbon and the rapid upward flow of the gases, which has the effect of giving a constant surplus of CO and of carrying CO₂ out of the field of action, tend to prevent the establishment of equilibrium, and to force the reactions to proceed in a direction that results in the final reduction of the iron oxides, with the consequent oxidation of either the C or the CO. Since the desired reactions are between solids and gases, the physical condition of the ore, especially its porosity and its particle size, play a part in either accelerating or retarding the reducing reactions. These same conditions, however, which tend to reduce the oxides of iron, prevent the complete oxidation of the CO to CO₂, because the CO, passing so rapidly over the stock—3 to 5 seconds to travel the height of the furnace in full blast—does not have time to become wholly oxidized, and the presence of the reducing agents, Fe, FeO, and C, tends to oppose the formation of CO₂. The escaping top gases, necessarily therefore, always show a large content of CO, much in excess of the CO₂ content. In modern furnaces, operating according to the prevailing practice with respect to coke consumption, the relative volumes of CO and CO₂ are approximately 2 to 1. In the lower part of the stack, the temperature is so high that CO₂ can exist but transiently, if at all, in the presence of carbon, and any oxide reduced in this region results in the gasification of a proportionate amount of carbon. This direct reduction of oxide by carbon is the most thermally inefficient mode of reduction, because it absorbs much heat, as shown by Reactions (8), (9), and (10), and robs the tuyere zones of carbon needed for combustion.

Tracing the Materials Through the Furnace—The ore, limestone, and coke, upon being charged into the top of the furnace, come in contact with an ascending current

of hot gases at a temperature of about 300°F (150°C). The first change that takes place is the physical one of drying, the hygroscopic water being driven off and carried out of the furnace by these gases. (Water of crystallization or chemically combined water is driven off from the various compounds in which it occurs in the range of temperature between 1300° and 1475° F). The stock, with its interstitial spaces filled with an ascending atmosphere containing the reducing gas CO, descends to regions of higher and higher temperatures. At different levels, then, chemical reactions peculiar to the temperatures of these levels occur. At first only the oxides of iron and carbon suffer change, and one of the first reactions to occur is number (4), in which carbon deposition may begin at a temperature as low as 575°F. In the presence of both C and CO, a large part of the remaining iron oxide, of small particle size, is next reduced at successive levels and at temperatures perhaps somewhat as follows:

At about 1457°F (800°C), the free iron is subject to reoxidation by CO₂, as are also the compounds, FeO and Fe₃O₄, though to a less degree, the chief action being represented by Reaction (5). These reactions and temperatures apply only to very fine ore. Lump ore, especially if it is not very porous, will descend to much higher temperatures before it is acted upon, the large, dense lumps may descend even to a level below the top of the bosh.

At 1475°F (800°C), or a little above, the decomposition of limestone takes place, thus: $\text{CaCO}_3 = \text{CaO} + \text{CO}_2$. This reaction is complete at 1830°F (1000°C). At 1650°F (900°C), carbon reduces CO₂ to CO, thus: $\text{C} + \text{CO}_2 = 2\text{CO}$, so that CO₂ does not exist normally below the 60-foot level. From this level the mixture is one of gangue, quicklime, coke, spongy iron, and varying amounts of unreduced ore, all of which descend to the fusion zone with very little change, if the absorption of carbon by the iron and the action of carbon on the unreduced ore be excepted. At this level, which is located at the top of the bosh, the lime combines with some of the gangue and, with a little unreduced iron oxide and manganese oxide, forms a part of the slag. The slag, such as already is formed, and the iron, both now in the liquid state, trickle down through the interstices of the coke to the hearth. In the hearth zone just above the tuyeres, where the metal and slag are in contact with hot coke, Reactions (11), (12), (13), (14), (17), (18) and (19), known as hearth reactions, occur. In the crucible, the slag and metal become separated by gravity, forming these two layers; a lower or metallic layer containing all reduced substances and an upper or slag layer containing all unreduced matter.

Conditions Affecting Silicon and Sulphur in the Metal—Reactions (13) and (19) should receive special attention, because of all the reactions that directly affect the quality of pig iron, these are the only ones the furnaceman can control. Both reactions depend upon two conditions, namely, temperature and basicity of slag. High temperatures favor the reaction, $\text{SiO}_2 + 2\text{C} = \text{Si} + 2\text{CO}$,

while a more highly basic slag retards it. Reaction (19), $\text{FeS} + \text{CaO} + \text{C} = \text{CaS} + \text{Fe} + \text{CO}$, requires lime and a high temperature. Therefore, high hearth temperature tends to raise the silicon content of the iron and lower the sulphur, provided the slag volume is adequate and the high temperature is obtained without the use of an excessive amount of high-sulphur coke. High basicity tends to lessen both the silicon and sulphur in the iron. In both instances, the extent to which the reactions progress under any given set of conditions is governed by time. The longer the time the farther they progress. This fact results in a difference in composition between

the first and the last metal in the same cast. Since the iron on the bottom of the furnace crucible is formed four or five hours before that on the top of the layer at the time of tapping, these reactions will tend to advance farther in the first than in the last iron formed under normal conditions. The first of the cast, therefore, usually will be found to contain a higher percentage of silicon and a lower percentage of sulphur than the last. This first iron is called **hot iron** on this account, because, as will be shown later, the oxidation of the silicon generates heat when the pig iron is purified, as in the Bessemer process, in the making of steel.

SECTION 7

THE BLAST-FURNACE BURDEN

The amounts of ore and stone charged per ton (or other fixed quantity) of fuel are referred to as the **burden**, the fuel or coke being constant in amount. Any increase in ore and stone above the normal is spoken of as a **heavy burden**, while the reverse of this results in a **light burden**. The regulation of the proportions of ore, flux, and coke is called **burdening**. It has two objects; namely, the most efficient operation of the furnace and at the same time the production of metal of the desired composition. The subject is of the greatest importance in the operation of a furnace, and is a

problem that may be solved either by practical experience or by calculations based on theoretical considerations.

Burdening the Furnace—With a furnace well started and on familiar materials, practical knowledge and experience alone may be sufficient to operate successfully. But in dealing with changing and unknown materials, it is necessary to resort to computed or "theoretical" burdening based on chemical composition. As illustrating the problems that confront the blast-furnace operator, the following will supply concrete examples:

Table 12—III. Representative Compositions of Raw Materials Used in the Blast Furnace (Dry Basis)

Elements and Radicals	Formula	Ores				Lime-stone	Coke
		(From Lake Superior District)					
		1	2	3	4		
		(%)	(%)	(%)	(%)		
Silica	SiO ₂	6.48	9.04	12.78	5.86	3.43	4.40
Iron	Fe	56.80	54.84	52.93	55.59	0.30	1.35
Manganese	Mn	1.14	1.09	0.83	0.16	0.08	0.07
Phosphorus	P	0.082	0.096	0.083	0.618	0.006	0.030
Alumina	Al ₂ O ₃	3.22	2.70	3.34	3.63	0.86	2.80
Lime	CaO	0.11	0.18	0.25	1.22	51.45	0.25

Chapter 13

EARLY PROCESSES FOR CONVERSION OF IRON INTO STEEL

SECTION 1

PROBABLE ANCIENT METHODS

It is probable that most of the steel produced in ancient times consisted of partially case-hardened wrought iron. Wrought iron, when heated and suddenly cooled by quenching in some liquid, will not harden because it does not contain enough carbon. By increasing the carbon content in the manner to be described, the outer portions and edges of a piece of wrought iron could be made to harden by heating and quenching.

The hardenable outer portion or "case" was produced by allowing a wrought-iron object to remain in a forge fire in contact with hot carbon, which completely surrounded it and protected it from oxidation. The carbon absorbed by the surface "layers" of the wrought iron would make it possible to obtain very hard surfaces and edges on a weapon, for example, by quenching the heated metal in a suitable liquid. The interior of the tool or weapon, of course, would remain relatively soft. Undoubtedly some steel was produced, intentionally or otherwise, when an imperfectly decarburized product was obtained from the South Wales, Lancashire, Wallow or similar processes. Another method, used in some of the Eastern countries to produce what very commonly is known as "Damascus steel," consisted of piling alternately pieces of soft iron on pieces of high-carbon iron and then heating, forging, fagoting and re-forging the billets. The layering that resulted from incomplete diffusion of carbon from the high-carbon bars into the low-carbon iron resulted in the surface appearance called "watering," which was characteristic of the so-called Damascus steels.

It is difficult to say how or when the first processes for intentional making of steel were developed. Archeological specimens from as far back as 1000 B.C. exhibit evidences of having been deliberately treated (case-hardened) to produce points and edges that were hardened by rapidly quenching the heated steel. One example is a chisel with a hardened point, found in one of the ancient cities of Ceylon and believed to date back to about 500 B.C. Early writers mention steel razors, surgical instruments, files, chisels and stone-cutting implements as early as several hundred years before the Christian Era.

The steel called *wootz* was produced in India for many centuries. Its method of manufacture has been variously

described. It is generally agreed that the first step consisted of heating pure ore with carbonaceous material such as charcoal or finely-chopped wood in closed crucibles. After heating at a high temperature for several hours, the ore was reduced to metallic iron and absorbed sufficient carbon from the excess of charcoal to have a low enough melting point to become fluid. The crucibles were allowed to cool and, when broken open, a small "button" of high-carbon steel was found at the bottom. Two methods have been recorded for lowering the carbon content of the buttons to give steel having the desired carbon content or "temper." One method consisted of repeatedly heating the buttons while they were covered with a layer of iron-oxide paste. The other recorded method comprised heating the buttons for several hours in a charcoal fire to a temperature not much below their melting point and turning them over in the path of the blast, so that the metal would be partially decarburized. In both cases, the partially decarburized buttons would then be heated to be welded together by hammering to form bars. Ambiguous records of various other processes for making steel by carburizing wrought iron appear in fragmentary literature from very early times.

In summary then, it may be said that prior to the invention of the Bessemer process for steelmaking in 1856 there were only two methods of making steel. One was the process of increasing the carbon content of wrought iron by heating it in contact with hot carbon away from air; this came to be called the **cementation process**. The other method, the **crucible process**, consisted of melting wrought iron in clay crucibles in which carbon had been added for the express purpose of increasing the carbon content of the iron. Both of these processes were certainly known to and practiced by the ancients.

During the Middle Ages both the cementation and crucible processes appear to have been lost to civilization. The cementation process was revived in Belgium about the year 1600 A.D. while the crucible process was rediscovered in England by Benjamin Huntsman in 1742. Both processes were practiced in secret for some time after their revival. Hence, little is known of their early history. The following brief descriptions will, therefore, be confined to practices in later years.

SECTION 2

THE CEMENTATION PROCESS

The cementation process was highly developed and flourished in England during the 18th and 19th centuries and, though it has practically been replaced by other methods, is still practiced to a limited extent. The

process depends upon the fact that when a low-carbon ferrous product, such as wrought iron, is heated to a red heat in contact with charcoal or other carbonaceous material, the metal absorbs carbon, which, up to the satura-

tion point of less than 2.00 per cent (about 1.70 per cent), varies in amount according to the time the metal is in contact with the carbon and the temperature at which the process is conducted. For carrying on the process, a type of muffle-furnace or pot-furnace is used, and the iron and charcoal are packed in the pots in alternate layers.

The iron used was usually in the form of bars 2½ inches to 3 inches wide, ⅝ inch to ¾ inch thick, and 6 to 12 feet long. For the best grades of steel, only the best wrought iron was supposed to be used, though low-carbon steel made by the open-hearth process was later substituted. Charcoal, which had been passed over about a ¼-inch screen to remove fines, represented the favorite carburizing agent, though various other substances and mixtures had been tried and used. In charging the pots, their bottoms were first covered with a layer of charcoal 2 or 3 inches thick, then, in alternation, layers of bars and charcoal were added to each until the pots were full. The bars were laid flatwise and about ½ inch apart, between edges, so that each bar was completely surrounded by charcoal. After applying the final layer of charcoal the charge was covered with wheel swarf (refuse from the grindstones) and all openings to the pots were closed and made nearly as airtight as possible. A fire was next lighted in the furnace, and the charge, for the next 3 or 4 days, gradually heated to a full red heat—the actual temperature varied from 1470° F to 2010° F (800° C to 1100° C) and this temperature was then maintained for 7 to 12 days, depending upon the size of the bars used, the carbon content desired, and the temperatures attained and maintained. The degree of carburization, or the temper of the bars, was determined by fracture tests on test bars that were withdrawn from the pots through small openings or holes provided for the purpose. When the bars had reached the desired temper, i.e., had absorbed the desired amount of carbon, the fire was banked and the furnace allowed to cool slowly. When the contents of the furnace were cool enough to handle, the bars were removed from the pots.

If the original bars were of wrought iron, their surfaces

were found to be covered with irregular elevations, known as blisters or beads, which resulted from the expansive force of the carbon monoxide formed by carbon reacting with the oxides of the incorporated slag. Hence, these bars were known as blister steel. If the original bars were of mild steel or remelted wrought iron, these blisters were absent. Both products were frequently referred to as converted or cement steel. If air had gained access to the bars during the process, their surfaces were covered with scale and almost decarburized. Such bars were known as aired bars. After sorting and reheating, the cement bars were hammered or rolled into what in England was called spring plate or bar steel, which formerly was used for springs, but later was used as raw material for crucible steel or for the production of shear steel. If for the latter, the bars were broken or sheared into short lengths, fagoted, sprinkled with a little borax, covered with clay, reheated to a welding temperature, and hammered into a bar, known as single shear. For purposes requiring a high grade, uniform steel, the single shear bars were again broken at their centers, the two halves of each laid together, and the fagot thus formed was reheated and hammered down to the required size. These bars were known as double shear steel. This steel was formerly used exclusively for the manufacture of cutlery, hence the name, shear steel.

This working was necessary to obtain the highly desirable homogeneity of the steel, and, prior to the revival of the crucible process, was the only method available to attain that end. Formerly, about seven grades or tempers of shear steel were produced. These varied in average carbon content from 0.50 per cent to 1.50 per cent. But as the carbon was absorbed from the surfaces of the bars, the carbon content of the blister steel bars progressively decreased to the center. In the softer grades the center portions of each bar remained unaltered, and this core was known as sap. In the harder grades, the outside of the bar might show a carbon content of 1.50 to 2.00 per cent with a center of 0.85 to 1.10 per cent. It was this characteristic of cement steel that led Huntsman, who was a clockmaker, to seek a method for making a more uniform steel for his springs.

SECTION 3

THE CRUCIBLE PROCESS

Realizing that the shortcomings of cement steel for springs lay in lack of homogeneity, Huntsman conceived the idea of melting it in crucibles, which melting he thought should make the steel perfectly homogeneous. Briefly, his method was as follows: First, cement bars were carefully selected that would give the exact temper, or carbon content, desired in the finished steel. These were cut or broken into small pieces. Then this steel was charged into large clay crucibles, which, after covering and luting the lids, were placed in a coke fire and heated until the contents were thoroughly fused. At this point the crucibles were withdrawn from the fire, and upon removing the cover and skimming off the small amount of slag formed on top, the molten metal was poured into a cast-iron mold, where it remained until solid. Finally, by the usual method of reheating and hammering then in use, the ingot was worked into the form desired. This method gave a steel that was not only homogeneous throughout, but was free from occluded slag and dirt, hence was so much superior to cement steel for many purposes that the method at once became the leader for the production of the finest steels. This position the process held for almost two hundred years, but today, at least in this country, it has been

superseded for the making of special alloy steels and carbon tool steels by the electric-furnace process, including the high-frequency induction furnace. The electric-furnace process is cheaper, is capable of giving as good steel, and possesses many metallurgical advantages over the crucible method.

Although the principles and the general method of procedure remained the same, the crucible process was the subject of considerable experimentation after the time of Huntsman, and some changes in the material of the charge, in the manufacture of the crucibles, and in the furnace for melting the crucible charges were introduced, so that the details of standard practice for this now practically extinct process in different countries and localities varied somewhat.

Manufacture of the Crucibles—The crucibles, or pots, were a very important part of the equipment required in the manufacture of crucible steel. As they were costly to make and had a comparatively short life, they were a large item of expense. In England, they were frequently made of clay by the steel manufacturer himself, but in this country so-called graphite crucibles were almost universally used. These crucibles, with a capacity of 80 to 124 pounds, varied somewhat in form and thick-

ness of wall. In general, they were barrel-like in shape, and varied in size from 13 to 18 inches in height and from 8 to 12½ inches in outside diameter at the bilge. As to wall thickness, they were somewhat thicker at the bottom than at the top, usually about 1½ inches at the bottom and about ¾ inch at the top.

The Crucible Melting Furnace—In this country, the crucible furnace was generally of the gas-fired regenerative type (Figure 13-1). It consisted of a number

CRUCIBLE

FIG. 13-1. Vertical section through checker chambers and one of the melting holes of a regenerative crucible furnace

of combustion chambers or melting holes built in a row between two sets of checker chambers. Each melting hole, about three feet in depth and otherwise large enough to hold 4 or 6 crucibles, was connected with the two sets of checkers by short flues leading upward from its bottom. If producer gas was used as fuel, the gas checkers were placed next to the line of melting holes with the air checkers extending along the outer walls of the furnace. This plan of construction readily permitted introducing the gas into the ports below the air, which was deflected downward by the roof, thus holding the flame near the bottom of the crucibles as it swept across the melting hole. In case natural gas, fuel oil, or powdered coal was used for fuel, both checkers would be used for air, or the furnace would be constructed with but one checker chamber on each side. The shop floor was on a level with the top of the melting hole, so that only the covers were visible from above. After moving these covers aside, the crucibles were lowered into and lifted out of the hole by tongs with broad jaws curved to fit the crucibles.

The bottoms of the melting holes were built of first-quality firebrick laid on plates, which were supported by beams, or cross bars, spanning the space between the two sets of checkers, thus forming a continuous cellar, or vault, that extended the full length of the furnace beneath the melting holes. A hole, some 4 or 5 inches in diameter, was provided in the center of the bottom of each melting hole, so that any refuse on the bottom of the melting hole could be poked into the vault below for cleaning. To protect the bottom in case of breakouts, it was covered to a depth of 6 to 8 inches with coke dust or crushed coke. This coke also gave some protection to the crucibles, as it helped to consume free oxygen not needed for combustion and to maintain a reducing atmosphere in the hole.

Charging the Crucibles—From what has already been said, it will be evident that, aside from the possible elimination of gases from the steel and the separation of slag and other non-metallic inclusions, the crucible process was not a purification process. Consequently,

any elements capable of alloying with iron charged into the crucible were present also in the steel. On this account the greatest of care in the selection of the raw materials had to be exercised. And it was characteristic of the history of the process that, once a charge that produced the kind or grade of steel desired had been hit upon by any shop, that charge was strictly adhered to and could not be varied. For many years after the introduction of the process by Huntsman, cement steel or blister steel was the only raw material used. Eventually, attempts were made to eliminate the cementation step by the use of wrought iron with charcoal; and, provided Swedish iron, which was the purest wrought iron then made, was used, the steel produced was as good as that made from cement bars. In 1801 David Mushet introduced the use of manganese, by adding oxide of manganese with the charge, which practice was superseded some years later by the use of *spiegel*. It is interesting to note that the use of *spiegel* in Bessemer steel was patented in 1857 by a namesake, Robert Mushet (this method of adding manganese was an important factor in the early development of Bessemer steel). Then followed a great deal of unsuccessful experimental work, involving so many different substances and mixtures that the stock house came to be known as the medicine house. Later, with the introduction of the Bessemer and acid open-hearth processes, efforts were made to reduce the cost by the substitution of soft-steel scrap for the Swedish wrought iron, but owing, perhaps, to the fact that miscellaneous scrap was used, which carried a higher content of manganese, phosphorus, and sulphur and was more variable in composition than the Swedish wrought iron, the steel was found to be of inferior quality. More recently, washed metal, that is semi-purified pig iron, freed from silicon, manganese, and phosphorus, had been used with excellent results to bring up the carbon of the wrought iron. Still more recently, owing to the introduction of the cheaper electric process and the difficulty of securing good wrought iron, recourse was had to the use of steel scrap, in part at least. With good basic or acid open-hearth mill scrap, the composition of which is more uniform than miscellaneous scrap and could be more readily controlled, steel of good quality could be made, provided proper care was taken to adjust the composition with the best wrought iron and washed metal.

All the practices just described had to do with carbon steels. Since the process had always been used in the production of the finest steels, especially tool steel, the introduction of alloy steels created the greatest diversity of practices. In making alloy steels, the old rule-of-thumb methods of charging had to be abandoned for other plans in which the composition of the charge could be accurately determined by chemical analysis. This applied particularly to high-speed tool steels, which, prior to the introduction of the electric process, could be made successfully only by the crucible process. At first, these steels were made from high-grade wrought iron or muck bar by the addition of the desired elements in the form of iron alloys, and the necessary recarburizer in the form of charcoal or washed metal. Later, tool scrap was used to make up a part of the charge, and much inspecting and many analyses were required to select the scrap and determine the proportions of the charge.

Stages of the Crucible Process—The materials for the charge, after they had been inspected and analyzed, were sheared or broken into small pieces, then carefully weighed out in proper proportions and amounts in the mixing house. These were carefully placed in the crucibles with the wrought iron or steel scrap on the bottom.

The crucibles were then tightly covered and taken to the melting hole, into which they were lowered vertically by tongs in the hands of a workman. The gas and air were then regulated to melt the charge as rapidly as possible without injuring the crucibles. The time of melting varied from 2½ to 4 hours, according to the composition of the charge and the heating conditions of the furnace. Low-carbon heats required more time than high-carbon, and high-speed steel required the most time of all grades. As the charge melted, and for some time after melting, the metal evolved gases, which finally collected in fairly large bubbles and broke slowly on the surface of the metal, producing the spectacle known as *cat's eyes*. The melter now watched each pot closely, and when the steel appeared to be dead, that is, free from gases and in a tranquil state, he signaled the puller-out, who grasped the crucible with the long broad tongs, lifted it out of the hole, and set it on the floor. The killing of the heat usually required 30 to 40 minutes, sometimes longer, and was an important part of the process, because the practice was necessary to give sound ingots. On the other hand, if the steel was kept in the furnace too long after it had reached the dead-melt stage, it would be damaged and might be ruined by absorption of too much carbon and silicon from the crucible. The temperature was also important; if the heat were pulled too cold, the steel would begin to solidify before it could be cast, and if it were cast too hot, the resulting ingot would not be sound. In some cases the pots were pulled before the steel was completely killed, and a little aluminum (not over 0.05 per cent) was added to the pot just before the steel was poured into the ingot mold. These methods of finishing affected the hardening properties of many of the steels made by this process.

Casting—The cover was then removed from the crucible and most of the slag was mopped or swabbed up by means of a ball of slag on one end of an iron rod. The crucible then was grasped horizontally with a pair of tongs, and, by tilting the crucible, the steel was poured into a cast-iron mold. This pouring required strength and skill, for it had to be continuous, and the stream of metal could not be permitted to impinge upon the walls of the mold. Any slag that might remain on the surface of the liquid metal was held back, by a small iron bar, and prevented from flowing into the mold. The molds were closed at the bottom and to facilitate the removal of the ingots after casting, split molds were used. These molds were cast in two pieces or halves, which fitted together by rings and wedges, formed a mold of square section with the joint passing longitudinally through diagonally opposite corners. Usually, the capacity of the molds was but a single potful of steel, and their cross section was but 3 or 4 inches square; but occasionally larger ingots were required, in which case two pots might be poured at once by the use of a funnel or spout made from a worn-out crucible, or several pots might be poured into a steel ladle, and the steel teemed into the molds from it. The last plan was followed in the production of fine steel castings of a size requiring more than two pots of metal. As soon as the steel had been poured, the crucible was cleaned and carefully inspected for cracks, when, if found sound and in good condition, it was charged, as before, for another heat.

Stripping and Inspecting the Ingots—As soon as the steel had solidified in the molds, the wedges or keys were loosened, and the rings holding the two parts of the mold together were removed. In the case of lower carbon steels, the mold might be removed at once and the ingot cooled in air, but ingots of high-carbon and alloy steels had to be cooled slowly to prevent the forma-

tion of clinks or tiny cracks, due to non-uniform distribution of contraction and expansion forces. Such ingots were allowed to stand in their molds until solid, then removed and placed in dry lime or covered with ashes or hot, dry sand until cold. The ingots were then topped, that is, pieces of their tops were broken off until the fracture showed perfectly sound steel. From the fractures thus exposed, the temper or carbon content (except in the cases of certain alloy steels) was determined. Then they were inspected for surface defects, and carefully and slowly reheated to a forging temperature. They were next forged, or clogged, under a hammer and any cracks or defects that appeared during the forging were ground or chipped out. After being forged to the required section, usually 1 to 2½ inches square, the billets were inspected again. Any surface defects, such as rough spots, seams, or tiny cracks were ground out with emery wheels, and these billets were reheated and rolled or forged into the sections desired. All this work was done with the greatest care, and was so meticulous as compared with the attention given ordinary steel that it was termed *crucible practice*.

Without doubt, crucible practice played as important a part in the high quality of crucible steel as crucible melting.

Chemistry of the Crucible Process—From a chemical standpoint, at least, the crucible process was the simplest of all for making steel. In the beginning, the charge carried a small quantity of iron oxides in the form of rust and scale and an almost negligible quantity of free oxygen in the air trapped in the crucible. As the charge melted, these oxides at first formed an oxidizing and very basic slag, which was soon reduced to the ferrous condition by the carbon in the charge or the crucible. Some ferrous oxide dissolved in the metal, and the remainder reacted with clay of the crucible to form ferrous silicates and ferrous aluminum silicates, which, after the charge had all melted and the temperature had been raised, absorbed more and more silica until the slag became very acid. In the meantime, the metal had been absorbing carbon, either from the crucible or the charcoal charged, and the conditions within the crucible now became strongly reducing. Any oxides dissolved or otherwise incorporated with the metal now reacted with carbon, forming carbon monoxide gas; and since the slag was very acid, silica was readily split off from the slag molecules and was at once reduced, forming silicon, which alloyed with the iron and entered the metal. The absorption of carbon and the reduction and absorption of silicon both progressed with time and temperature, and were more rapid in new crucibles than in crucibles that had been used. The presence of silicon in the metal had the effect of cleansing it of oxides, and, without doubt, it was a large factor in "killing" the steel; but after a content of 0.50 per cent was exceeded, it began to have a noticeable embrittling effect upon most steels. Silicon also affected the welding and certain other properties adversely, hence was positively undesirable in some steels, a difficulty overcome by partial substitution of aluminum. This change in the deoxidizer used sometimes was made for the purpose of controlling the hardening properties of the steel. Hence, the time of killing as well as the temperature had to be closely watched, but it is evident that close control of either of these factors was impossible, with the result that both the carbon and the silicon contents might vary over relatively wide limits. To produce a large quantity of steel of uniform composition, say up to one ton, it was necessary to pour a number of these 100-lb. crucible melts into a ladle in such a manner that the metal would be thoroughly mixed.

SECTION 4

MODERN STEELMAKING PROCESSES

All of the processes discussed in the earlier parts of this chapter were destined eventually to be supplanted by entirely new methods of steelmaking. The first of these new methods was the **pneumatic or Bessemer process**, which first found commercial application in 1860. By this process the excess amounts of carbon, manganese and silicon present in pig iron are removed by blowing ordinary air through a shallow bath of liquid pig iron. The unwanted elements are literally "burned" out of the bath by combining with oxygen in the air blast. In a typical 25-ton **converter**, as the vessel in which this process is carried out is called, this amount of liquid pig iron can be converted into steel in 12 to 15 minutes of actual blowing with air. The great advantages of the process over earlier methods are: (1) its speed, (2) the fact that the refined steel is obtained in liquid form, and (3) the amount of liquid steel produced per operation is very much greater than that produced by any earlier method. The complete history of development of this process is discussed in Chapter 14

Closely following the invention of the Bessemer process was the development of the **regenerative-type furnace**. Originally designed by Karl Wilhelm Siemens for work in steam generation, glass melting, and in heating furnaces, the regenerative furnace was capable of attaining such high temperatures that it naturally suggested itself for use in steelmaking. In this service, it became known generally as the **open-hearth furnace**. Eventually, the open-hearth furnace was destined to become the chief means for producing steel throughout the world. Its historical development is described in Chapter 15.

The **electric furnace** is relatively a newcomer to the field of steelmaking and is gradually finding more and more applications in the quantity production of quality steels. There are various ways in which the electric current can be made to generate the heat required for steelmaking operations. The development of furnaces that employ these several methods, and the design and operation of modern electric steelmaking furnaces are discussed in Chapter 16.

Chapter 14

THE PNEUMATIC STEELMAKING PROCESSES

SECTION 1

INTRODUCTORY

General Principles of Steelmaking—Pig iron consists of the element iron combined with numerous other chemical elements, the most common of which are carbon, manganese, phosphorus, sulphur and silicon. Depending upon the chemical composition of the raw materials used in the blast furnace—principally iron ore, coke and limestone—and the manner in which the furnace is operated, pig iron may contain 3.0 to 4.5 per cent of carbon, 0.15 to 2.5 per cent or more of manganese, as much as 0.2 per cent sulphur, 0.025 to 2.5 per cent of phosphorus, and 0.5 to 4.0 per cent of silicon. In refining pig iron to convert it into steel, all five of these elements must either be removed almost entirely or at least reduced drastically in amount.

Modern steelmaking processes, including the pneumatic processes, are divided into two general classes from the chemical standpoint; acid processes and basic processes. Carbon, manganese, and silicon can be removed with relative ease by any of the processes, either acid or basic. The removal of phosphorus and sulphur requires special conditions that can be met only by the basic processes wherein lime is added to the chemical system to form a basic slag which is capable of forming compounds with phosphorus and sulphur during refining operations, thereby removing them from the metal. Because of the chemical nature of the slags, each of the processes must be carried out in equipment lined with proper refractories. Otherwise, the slags would react with and be neutralized by the lining material while, at the same time, rapidly destroying the lining.

In general, the chemical principle of oxidation is employed to convert pig iron into steel. Each of the steelmaking processes has been devised primarily to provide some means whereby controlled amounts of oxygen can be supplied to the molten metal undergoing refining. The oxygen combines with the unwanted elements (with the exception of sulphur) and, unavoidably, with some of the iron, to form oxides, which either leave the bath as gases or enter the slag. The mechanism by which sulphur is removed does not involve direct reaction with oxygen but depends instead on whether the slag is sufficiently basic and high enough temperatures are attained. As purification of the pig iron proceeds, the melting point of the bath is raised, and sufficient heat must be supplied from some source to keep the bath molten.

Principles and Types of Pneumatic Processes—In common with other steelmaking methods, there are two chemical types of pneumatic processes—acid and basic. In both types, air, high-purity oxygen or combinations of these and other oxidizing gases are blown, under pressure, through, or over the surface of, molten pig iron to produce steel. If air alone is used for blowing, its nitrogen content serves little useful purpose and ac-

tually removes useful heat from the system. In some cases, nitrogen absorbed during blowing is considered as an undesirable impurity in the finished steel. There are three ways in which the oxidizing gas can be supplied to a pneumatic converter; these are shown schematically in Figure 14—2. The manner in which the oxidizing gas is introduced affects both the relative rates of the refining reactions and the product. The **bottom-blown converter** has been the principal type used in both the acid and basic pneumatic processes for the production of steel ingots (see Sections 2 and 3), the blast traveling the full depth of the bath, thus representing the extreme of submerged blowing practices. The **side-blown converter** can be arranged for either submerged or surface blowing, and significantly different performance characteristics obtain for the two arrangements. The submerged-side-blown converter presents a number of difficult maintenance problems and the design has not been popular, although in recent years a few Thomas converters have been modified to introduce the blast through the side of the vessel. A discussion of the aims and results of the Thomas modification will be found in Section 3. At present the only side-blown converters in extensive commercial use are acid-lined vessels arranged for surface blowing, and these are used chiefly in foundries to produce steel for castings (see Section 4). While basic-lined versions of these foundry converters have never been successful, considerable experimentation has been underway for some time in the United States and several foreign countries to develop a commercially useful side-blown pneumatic process, using a basic-lined converter, for the production of ingots; none of these has yet attained commercial status, so they will not be discussed further in this book. The last variety of surface-blown converter can be termed **top-blown**, the oxidizing gas being introduced by a pipe or lance through the mouth of the vessel. Bessemer and other early investigators employed this or a similar arrangement in some of their designs, and these practices are being used at the present time, chiefly by surface blowing with a high-velocity jet of high-purity oxygen (see Section 5).

Historical Development—The original pneumatic process, developed independently by William Kelly of Eddyville, Kentucky, and Henry Bessemer of England, involved blowing air *through* a bath of molten pig iron contained in a bottom-blown vessel lined with acid (siliceous) refractories. The process was the first to provide a large-scale direct method whereby pig iron could rapidly and cheaply be refined and converted into liquid steel. Bessemer's American patent was issued in 1856; although Kelly did not apply for a patent until 1857, he was able to prove that he had worked on the idea as early as 1847. Thus, both men held rights to the process

THE BESSEMER CONVERTER

(THIS DRAWING IS ENTIRELY SCHEMATIC AND NOT TO SCALE)

THIS IS NOT AN ENGINEERING DRAWING. THE VARIOUS PIECES OF EQUIPMENT ARE NOT DRAWN TO THE SAME SCALE. THE SKETCH IS INTENDED ONLY TO SHOW THE MAJOR EXTERNAL FEATURES OF TWO SEPARATE BESSEMER STEELMAKING PLANTS AND THEIR AUXILIARIES, THE POSITIONS OF CONVERTERS AT VARIOUS STAGES OF "BLOWS" AND DISPOSITION OF THE FINISHED STEEL.

FIG. 14-2. Entirely schematic representation, not to scale, of the three ways in which air and/or oxygen can be supplied to pneumatic converters. Horizontal dotted lines represent approximate level of bath. Dotted circles indicate approximate location of trunnions on which vessels can be rotated.

in this country, this led to considerable litigation and delay, as discussed later. Lacking financial means, Kelly was unable to perfect his invention and Bessemer, in the face of great difficulties and many failures, developed the process to a high degree of perfection and it came to be known as the acid Bessemer process, described in its modern form in Section 2.

The fundamental principle proposed by Bessemer and Kelly was that the oxidation of the major impurities in liquid blast-furnace iron (silicon, manganese and carbon) was preferential and occurred before the major oxidation of iron; the actual mechanism differs from this simple explanation, as outlined under "Chemistry of the Acid-Bessemer Blow" in Section 2. Further, they discovered that sufficient heat was generated in the vessel by the chemical oxidation of the above elements in most types of pig iron to permit the simple blowing of cold air through molten pig iron to produce liquid steel without the need for an external source of heat. Because the process converted pig iron to steel, the vessel in which the operation was carried out came to be known as a converter.

At first, Bessemer produced satisfactory steel in a converter lined with siliceous (acid) refractories by refining pig iron that, smelted from Swedish ores, was low in phosphorus, high in manganese, and contained enough silicon to meet the thermal needs of the process. But, when applied to irons which were higher in phosphorus and low in silicon and manganese, the process did not produce satisfactory steel. In order to save his process in the face of opposition among steelmakers, Bessemer built a steel works at Sheffield, England, and began to operate in 1860. Even when low-phosphorus Swedish pig iron was employed, the steels first produced there contained much more than the admissible amounts of oxygen, which made the steel "wild" in the

molds. Difficulty also was experienced with sulphur which, introduced from the coke used as fuel in melting the iron in cupolas, contributed to "hot shortness" of the steel. These objections finally were overcome by the addition of manganese in the form of spiegeleisen to the steel after blowing was completed. The beneficial effects of manganese were disclosed in a patent by R. Mushet in 1856. The carbon and manganese in the spiegeleisen served the purpose of partially deoxidizing the steel, while part of the manganese combined chemically with some of the sulphur to form compounds that either floated out of the metal into the slag, or were comparatively harmless if they remained in the steel.

Because of trouble with tuyeres in the bottom, some early converters had tuyeres located in the side of the vessel but below the metal-bath surface. Many of the early converters were stationary and had to be tapped in a manner similar to the cupola or the open-hearth furnace; such converters were used for a considerable period in Sweden and Germany. However, the rotating or tilting type was favored in England and in the United States.

As stated earlier, Bessemer had obtained patents in England and in this country previous to Kelly's application; therefore, both men held rights to the process in the United States.

The Kelly Pneumatic Process Company had been formed in 1863 in an arrangement with William Kelly for the commercial production of steel by the new process. This association included the Cambria Iron Company; E. B. Ward; Park Brothers and Company; Lyon, Shord and Company; Z. S. Durfee and, later, Chouteau, Harrison and Vale. This company, in 1864, built the first commercial Bessemer plant in this country, consisting of a 2½ ton acid-lined vessel erected at the Wyandotte Iron Works, Wyandotte, Michigan, owned by Captain

E. B. Ward. It may be mentioned that a Kelly converter was used experimentally at the Cambria Works, Johnstown, Pennsylvania as early as 1861.

As a result of the dual rights to the process a second group consisting of Messrs. John A. Griswold and John F. Winslow of Troy, New York and A. L. Holley formed another company under an arrangement with Bessemer in 1864. This group erected an experimental $2\frac{1}{2}$ -ton vessel at Troy, New York which commenced operations on February 16, 1865. The rival organizations, after much litigation had failed to gain for either sole control of the patents for the pneumatic process in America, decided to combine their respective interests early in 1866. This larger organization was then able to combine the best features covered by the Kelly and Bessemer patents, and the application of the process advanced rapidly.

By 1871, annual Bessemer steel production in this country had increased to 45,000 net tons. This comprised about 55 per cent of the total steel production of the country, and was produced by seven Bessemer plants.

A. L. Holley's contributions to the early development of the process were exceedingly important. He acted as consulting engineer on most of the plants erected in the first ten to fifteen years of the development of the process in the United States. Holley also greatly improved the design of the detachable bottom, originally developed by Bessemer in 1863; this permitted increased tonnage output because it permitted replacement of the bottom when repairs were necessary without excessive loss of production.

A process involving the use of a basic lining and a basic flux in the converter, which made it possible to use the pneumatic method for refining pig irons smelted from the high-phosphorus ores common to many sections of Europe, was patented in England in 1879. The process, known as the Thomas, Thomas-Gilchrist or basic Bessemer process, is described in Section 3.

Another notable contribution to development of the pneumatic processes was made at a later date (1889) by William R. Jones of the Edgar Thomson Works of the Carnegie Steel Co., now a part of United States Steel Corporation, who conceived the idea of the hot-metal mixer. The purpose of the mixer and its construction are described in Section 2.

Characteristics of Pneumatic Steels—While the pneumatic steelmaking methods possess the advantages of speed and simplicity, there are certain chemical disadvantages common to both the acid and basic processes.

For example, bottom-blown acid Bessemer steels are generally higher in phosphorus, sulphur and nitrogen contents than basic open-hearth steels. Steels produced by the bottom-blown basic pneumatic processes may approach basic open-hearth steels with respect to phosphorus and sulphur contents, but it is more difficult to produce steel of low nitrogen content by this process. When their phosphorus, sulphur and nitrogen contents are high in comparison with basic open-hearth steels, steels produced by the pneumatic processes possess higher yield and tensile strengths and lower ductility than the open-hearth steels. Further, when the nitrogen content is high, pneumatic steels are subject to some loss of ductility due to aging. When air alone is used for blowing, bottom-blown vessels produce steel with the highest nitrogen content, side-blown vessels produce steel possessing intermediate nitrogen content, and top-blown vessels produce steel with the lowest nitrogen content. Another disadvantage of most pneumatic steels is the inability to control carbon and oxygen contents of the finished steels as closely as can be accomplished in the basic open-hearth process. Because of the nature of pneumatic processes, it is presently impossible to closely control the final carbon content of pneumatic steels by stopping the blow at the exact time when the carbon content has fallen to the desired level, except at very low levels of carbon content. This generally limits the variety of steels made to those containing 0.30 per cent and less carbon (although commercial steels containing up to 0.50 per cent carbon are produced). The higher-carbon steels are made by blowing the metal to a consistently low carbon content and then adding the required amount of carbon in the form of recarburizers. In addition to the control of carbon, some difficulty is also experienced in controlling the final temperature and state of oxidation of pneumatic steels.

In general, steels which have similar chemical compositions have similar physical and mechanical properties. Steels made by pneumatic steelmaking processes which have the same chemical composition as those made in the basic open-hearth furnace, particularly with regard to phosphorus, sulphur, nitrogen and other contents, will have properties quite similar to the basic open-hearth steels and may be used in the same general applications. There are some applications where pneumatic steels, particularly those produced by the acid Bessemer process or variations of it, are superior to steel produced by any other method because of the desirable mechanical and physical properties resulting from the chemical composition of the pneumatic steels.

SECTION 2

THE BOTTOM-BLOWN ACID PROCESS

As has already been stated, the bottom-blown acid process now known generally as the acid Bessemer process was the original pneumatic steelmaking process. Many millions of tons of steel have been produced by this method. From 1870 to 1910, the acid Bessemer process produced the majority of the world's supply of steel.

The success of acid Bessemer steelmaking is dependent upon the quality of pig iron available which, in turn, demands a reliable supply of relatively high purity ore and good metallurgical coke. At the time of the invention of the process, large quantities of this type of ore were available, both abroad and in the United States. With the gradual depletion of supplies of high-quality ore (particularly low-phosphorus ores) abroad and the rapid expansion of the bottom-blown basic pneumatic and basic open-hearth processes of steelmaking, acid

Bessemer steel production declined to a very low level percentage-wise, particularly abroad in the early twentieth century. Sweden and Great Britain are the only European countries with adequate reserves of ores suitable for the production of steels by the acid Bessemer process.

In the United States, the Mesabi Range has provided a source of relatively high grade ore for making iron for the acid Bessemer process for many years. In spite of the availability of good ore in this country, the acid Bessemer process has still declined from a major to a minor steelmaking method in the United States. The reasons are partly metallurgical and partly economic.

The early use of acid Bessemer steel in this country involved production of a considerable quantity of rail steel, and for many years this process was the principal

method used for the production of steel, as shown by Table 14—I. At the present time, the acid Bessemer process in the United States is used principally in the production of steel for butt welded pipe, seamless pipe, free-machining bars, flat-rolled products, wire, steel castings, and blown metal for the duplex process. The rated converter capacity of the nation is approximately 12,000,000 tons of steel. Over half of this capacity represents blown metal for use in the open-hearth or duplex process and the remainder Bessemer ingots. Most of the steel in this country is manufactured by the open-hearth process, and during the past few years few new converters have been installed, although extensive experimental work on converter steel is in progress. The inherent advantages of the process involve economic considerations in times of peace and national security in times of war. Fully-killed acid Bessemer steel was used

for the first time commercially by National Tube Division of United States Steel Corporation in the production of seamless pipe. In addition, dephosphorized acid Bessemer steel has been used extensively in the production of welded pipe and galvanized sheets.

The modern shop for using the acid Bessemer process usually is built in conjunction with basic open-hearth furnaces to take advantage of the so-called "duplex" process (see Chapter 17). Since the production of duplex steels is covered in a later chapter, the present discussion is confined to that part of the Bessemer converter tonnage manufactured as acid Bessemer steel in ingot form.

PRINCIPAL FACILITIES

Plant Layout—Newer installations usually consist of three bottom-blown converters, also called vessels, of

†The figures for 1934 and subsequent years include only that portion of the steel casting production which was produced in foundries operated by companies producing steel ingots.

from 25 to 30 tons capacity, one of which is maintained as a spare. The shop is on three levels with the pouring floor at ground level. Two sets of standard-gage track service the vessels. The first set runs along the back of the shop with spurs running under each vessel. On these spurs are placed the slag pots and, when it is necessary to change bottoms, the bottom-hoist car. The other tracks run in front of the vessels and are used to position the ladles. A teeming floor, with the necessary cranes for handling the ladles from the cars, is located close to the converter shop.

On the second level are located the vessels, vessel-repair car and the iron-transfer ladle car to carry the molten metal from the mixer to the vessels (Figure 14-3). To the side of the shop are located the mixers and the bins for ferromanganese and other ladle additions. On the same level, but located across the shop from the vessels, is the control pulpit. On the third level are the tracks for ladle cars used to fill the mixers, the mixer controls and scales for the iron-transfer ladle.

The Air Blast—Adjacent to the converter building is located the blowing room, wherein the air blast is generated by turboblowers, although in older shops, steam-driven, vertical, reciprocating-type blowing engines are still in use. The blast is carried into the converter building through large mains which lead to the hollow trunnion of each vessel. Each line is fitted with control valves which are regulated from the pulpit by the blower. Also

connected to each air-blast line is a steam line fitted with valves for injection of steam into the blast for temperature-control purposes. These valves also are regulated from the blower's pulpit. The pressure in the main is regulated by an automatic blow-off valve, which functions when the vessel is off blast during charging or pouring. Blast pressures normally range from twenty to twenty-five pounds per square inch. Pressures up to thirty-five pounds per square inch are used on larger vessels. Although pressures as low as eighteen pounds per square inch are sufficient to prevent the molten iron from entering and blocking the tuyere holes, the use of this low pressure would prolong the blowing time unnecessarily.

Pressures over the indicated maximums are not used because of the large amount of metal which would be ejected from the converter during blowing.

Bottom House—The bottom of the converter is the part subject to the most wear and requires frequent replacement. Adequate facilities must be provided to insure a constant supply of rebuilt bottoms. These facilities include adequate storage bins or hoppers for the refractories used, equipment such as pug mills for the grinding and mixing of the refractories, pneumatic tools for ramming the bottom material in place, a storage area for tuyeres, and ovens for drying the completed bottoms. These ovens may be either of the in-and-out batch type or tunnel ovens of the continuous type.

FIG. 14-3. General view of a recent installation of Bessemer converters, showing one of the three vessels blowing. Slag pots and the bottom-hoist car operate on standard-gage tracks on the level beneath the vessels.

FIG. 14-4A. (Above) Diagram illustrating the details of construction that permit air to enter the converter through a hollow trunnion, so that the vessel can be turned down without interrupting the flow of air. This schematic diagram is not intended to show actual details of vessel construction, many of which are visible in Figure 14-5, showing an actual converter in operation. (See also Figure 14-4B).

THE CONVERTER OR VESSEL

The cylindrically shaped vessel consists of a steel shell of riveted or welded construction, supported on two horizontal trunnions upon which it can be made to rotate in a vertical plane (Figures 14-4 and 14-5). One of these trunnions is hollow, through which the blast is passed by a pipe called the gooseneck or elbow pipe, to the windbox at the bottom of the vessel. A pinion is fastened to the other trunnion and engages an electrically operated rack to tip the converter. The bottom, which is detachable, is pierced with twenty-eight tuyeres—larger vessels have as many as thirty-five—through which the air blast passes from the wind-box into the metal bath.

Refractory Lining—With the vessel in the inverted position, the steel shell is lined with siliceous stone. Cut and dressed sandstone (firestone) or micaceous schist is used, most operators preferring a combination of the two. The micaceous schist usually is placed in those areas of the lining subject to the most mechanical wear. This stone has a laminated structure composed of tiny plates of mica, and, when laid in such a manner that the edges of the laminations are exposed as the wearing surface, it is very durable. The stone is laid up tightly

with a thin layer of refractory fireclay and keyed into position to insure against movement when the vessel is tilted. Micaceous schist contains about 90 per cent silica, 3 to 7 per cent alumina and 2 to 4 per cent iron oxide; while sandstone is composed of approximately 93 per cent silica and about 4 per cent alumina, the remaining 2 to 3 per cent being iron oxide, lime and magnesia. Linings of this type have a life of approximately 25,000 tons of steel ingots. The linings are dried before using by a flame inside the vessel, supplied by a "lance" burning gas or oil that is inserted through the mouth of the converter.

Bottom Design—The tuyeres which admit the air blast from the wind-box into the vessel proper are cylindrical in shape, ranging in length from 26 to 36 inches depending on the size of the vessel. They are made of a good-quality fireclay, medium burned. Soft tuyeres deteriorate rapidly during blowing and decrease bottom life, while hard-burned tuyeres are too friable. The most commonly used tuyere is one containing seven $\frac{5}{8}$ -inch diameter holes which run the length of the tuyere block. The tuyeres are slightly mushroomed on one end, so that, when inserted through the tuyere plate, they form a tight fit. The tuyeres are arranged in the bottom usually in two or more concentric circles with one tu-

FIG. 14-4B. Plan of bottom and section through a 25-ton eccentric Bessemer converter, so-called because of the location of the opening in the nose. Concentric converters have the nose opening parallel to and concentric with the bottom.

yere in the center. On making a bottom, the tuyeres are set in position protruding through the cast tuyere plate. The large ring-shaped castings comprising the structural part of the bottom are used repeatedly over long periods of time. Extra bottom castings are, of course, available so that new bottoms can be in the process of being built while the converting mill is operating.

After positioning the tuyeres, long rectangular tile brick are positioned vertically throughout the bottom. The number used may vary anywhere from as few as six to as many as forty per bottom. It is felt that these tile brick act as stiffeners and prolong the bottom life. The number used must be balanced against the expected increase in bottom life, since their use increases the cost of the bottom.

The spaces between tuyeres and tiles are then filled with a refractory material suitably ground and moistened in a pug mill. The bottom material, consisting of siliceous stone such as ganister, brickbats and clay together with reclaimed material from spent bottoms, all thoroughly ground and mixed together, is shoveled into place and rammed solidly, particularly around the tuyeres, to form a compact mass. This constitutes the so-called **dry bottom**, which is then thoroughly dried and baked in the ovens for a minimum of forty-eight hours at temperatures ranging from 300 to 400° F to insure complete drying. Some operators prefer a **wet bottom**, in which materials are moistened to the consistency of a concrete and poured much in the same manner. Longer drying cycles and higher temperatures are required for this type of bottom.

Life of Bottoms—The bottom of the converter, as already stated, is subject to severe wear. On the average, bottom life will range only from twenty-five to thirty-

five "blows" for a plant whose total output is mixed steel ingots and duplex metal. The vesselman examines the bottom periodically while the vessel is inverted. If he notices that a particular tuyere is wearing more rapidly than the other tuyeres, which is referred to as **boring**, and thus endangering the life of the bottom, he will direct the removal of the plate from the bottom of the wind-box. The bad tuyere will then be plugged with a blanking plate or clay to prevent the blast from passing through it. As many as ten or twelve tuyeres may be so blanked before the bottom is replaced.

Once a tuyere begins boring, deterioration will proceed at an exceedingly fast rate, sometimes as much as one inch per minute. An explanation for boring that has been advanced is the possibility that the holes in the tuyere were not spaced symmetrically. As a result of two tuyere holes being abnormally close together a cavity may form in the tuyere end. This cavity would be filled with a small pool of metal because of the localized reduction of effective blast pressure. The small pool would be set in rapid motion by the blast and the metal would become highly oxidized and super-heated. In this condition it would be highly corrosive and chemical attack on the tuyere material would result. Once this reaction had started it would proceed at an increasing rate, thus causing rapid deterioration of the tuyere.

The bottom is changed when the tuyeres are worn down to a length of about eight inches. The change requires approximately thirty minutes. The bottom plate of the wind-box is removed. A small car is set in position under the vessel, and the vessel is turned to the vertical position. A hydraulic jack raises the car until it contacts the bottom. The keys holding the bottom in

FIG. 14-5. Close-up view of a Bessemer converter during the progress of a "blow."

place are knocked out, the connecting links disengaged, and the bottom allowed to settle on the car. The car is then lowered to ground level and pulled out of position by a standard-gage locomotive. The new bottom, mounted on a similar car, is placed in position, and the operation reversed.

Cupolas—Many of the earlier Bessemer plants were small, isolated units often located some distance from the source of pig iron. To supply the liquid-iron charge required by the process, solid pigs of iron were melted in reverberatory furnaces, superseded in a short time by cupolas. The cupola is a cylindrical stack-type furnace into which successive layers of coke, pig iron and limestone are charged at the top. A cold-air blast produced by fans, under a pressure of six to ten ounces, is introduced into the bottom of the furnace above the hearth through tuyeres located symmetrically around the circumference. The cupola consists of a steel shell, lined with firebrick in its upper part and firestone in the lower part which is subjected to higher temperatures. The temperature generated at the tuyeres by combustion of the coke is sufficient to melt the iron and also superheat it. The limestone, having calcined in the stack, also fuses, combining with the ash in the coke to form a slag. The molten iron accumulates in the hearth from which it is drawn periodically, depending on the requirements of the converter, by opening the tap hole and allowing the iron to flow by way of a spout into the transfer ladle. Spiegel, a high-manganese pig iron, containing about 5 per cent carbon, formerly was melted in a similar manner and was used to recarburize the blown metal.

The use of the cupola had certain inherent disadvantages which from the standpoint of production and quality control were most undesirable. Much of the sulphur and phosphorus in the coke was absorbed by the iron. These elements being undesirable above certain limits in the steel, and the acid process being incapable of removing them, it was necessary to use the best type of coke available. For this reason, as well as for economy, the amount of coke charged was held to a minimum. These factors, combined with fluctuations in iron composition, caused erratic swings in iron temperatures, resulting in difficulties in controlling the blowing of the converters. The desirability of using molten iron from blast furnaces became apparent at an early date, but the intermittent casting of the blast furnace, coupled with the large amount of molten metal taken from the furnace at one time, made such practice impracticable until the hot-metal mixer was invented. The advantages of the hot-metal mixer described below were quickly recognized in the industry and, at those plants where sufficient blast-furnace facilities were available, it replaced quickly those cupolas used for melting iron for blowing in the converters.

Hot-Metal Mixer—The fundamental purpose of the hot-metal mixer is to store molten iron from the blast furnaces until it can be used in the Bessemer converters or in the open-hearth furnaces. A modern mixer is illustrated in Chapter 15.

The modern plant usually has two or three mixers of from 200 or 300 to 1500 tons capacity. The mixer is a large, cylindrical vessel mounted horizontally upon two sets of races and rollers, which in turn are set upon firm foundations of concrete. The vessel is rotated about its central axis by an electric motor connected through reduction gears to a large screw, which actuates the vessel through a connecting rod attached to its bottom. The vessel is constructed of steel plates joined together to form a shell, which is lined with a good grade of fire-clay brick or micaceous schist. The lining is usually

about two feet in thickness. It is not uncommon for a mixer to be in continuous operation for a year before it is necessary for it to be drained in order to repair the lining. Complete relining is necessary about every three to four years. Molten iron is received from the blast furnace in ladles mounted on cars. These ladles are heavily insulated to conserve heat and are filled and emptied through a hole on the top. Molten iron is poured out of this hole into an opening on top of the mixer by revolving the ladle on its trunnions. On the front of the mixer is a second opening provided with a spout which permits hot metal to be drawn off as required by turning the vessel. The mixer, acting as a reservoir for molten iron, serves these useful purposes:

1. It conserves the heat in the molten pig iron, and is capable of maintaining the iron in the molten condition for long periods of time. Many mixers are equipped with gas- or oil-fired burners inserted in the ends, whereby additional heat can be made available if necessary.
2. It promotes uniformity of iron by mixing the product of several blast furnaces, thus equalizing the irregularities of individual casts. This permits delivery of iron of more uniform composition and temperature to the converters, which enables the blower to control steel-making variables more closely.
3. Because of its large capacity, it can permit independent operations between the blast furnaces and the converter shop to a large extent, since any ordinary delay in the operations of either unit will not affect the other seriously.

OPERATION OF THE PLANT

Sequence of Operations—After completion of the previous blow, the vessel is turned on its trunnions until it assumes an almost horizontal position and scrap, scale, or ore is dumped into the vessel as desired. The molten pig iron is then poured in from the transfer ladle, as shown schematically in Figure 14-6. In this horizontal position the metal is contained in the belly of the converter and does not come in contact with the tuyeres. The blast is started and the vessel is turned to a vertical position and remains in this position throughout the balance of the blowing period, unless "side blowing" is resorted to for increasing temperature, as discussed below.

The Bessemer blow is usually thought of as being divided into three parts, the first period, the second period and the after blow.

The first period, or the **silicon blow**, as it is commonly called, begins as the blast is turned on and the vessel turned up. During this period of the blow, a short, transparent flame extends from the mouth of the vessel. As the blowing continues the flame starts to lengthen after about four minutes and the second period or **carbon blow** begins.

The long, brilliant flame which is characteristic of the carbon blow continues until the elimination of carbon approaches completion, whereupon there is a definite change in the appearance of the flame. The flame gradually shortens in length and seems to fan out. As viewed through the blower's colored glasses, streaks of red appear in the flame at the mouth of the converter, and then almost instantaneously the whole flame changes from the usual golden yellow to a reddish-appearing flame. This change, which always occurs at almost the same carbon content from blow to blow, has been designated as the **end point**. As such it has been established as a control reference point by the blower. On some

POSITIONS OF BESSEMER CONVERTER AND CONTENTS DURING VARIOUS OPERATIONS

FIG. 14-6. Positions assumed by the Bessemer converter when [left] pouring molten pig iron into the vessel, [center] blowing compressed air through the molten metal, and [right] pouring the refined metal [steel] into the ladle whence it is poured into ingot molds. The bottom left sketch shows how tilting the vessel raises the tuyeres above the level of the molten pig iron charged into the converter. The bottom center illustration is drawn to indicate the highly turbulent condition of the molten metal due to the passage of gases during the blow. Note that some slag, not indicated on the drawings, accompanies the molten metal.

grades of steel the blow will be terminated promptly on reaching the end point. These blows are then said to be **young blown** heats. In other cases, it is necessary to prolong the blowing beyond this point as long as fifteen or twenty seconds. The time interval from end point to turn down is referred to as the **after blow**, and heats handled in this manner are said to be **full blown**.

It is during the second period that the flame attains its full brilliance and length, extending as much as thirty feet beyond the mouth of the converter. This flame results from the evolved carbon monoxide burn-

ing to carbon dioxide as it comes in contact with the air at the mouth of the converter. It is at this time that the blower carefully studies the flame to determine if his judgment regarding temperature control, and in estimating the amount of scrap needed, initially was correct. If the flame shows brilliant white patches and is extremely feathery around the edges, the temperature in all probability is too high. By introducing steam into the blast line the temperature can be lowered because of the heat absorbed through the dissociation of water vapor. A dull flame streaked with dark patches is indicative of low temperature. The temperature can be increased by resorting to **side blowing**. This involves tipping the converter over on its back, thereby exposing several of the tuyeres above the metal bath. By so doing, oxidation of carbon monoxide to carbon dioxide is promoted within the vessel itself, thereby increasing the temperature of the bath by the radiation of heat.

Darken and Gurry have calculated the comparative effect of various coolants used in the process to control temperatures (Table 14-II).

Table 14-II. Effect of Coolants in Bessemer Blowing

Addition of 100 lbs.	Cooling Effect Produced
Pig iron	42,000 Btu
Steel scrap	59,000 Btu
Dry ore	161,000 Btu
Steam or water vapor	415,000 Btu

FIG. 14-7. Curves showing relationship between the carbon content and iron-oxide content of the metal in a converter.

Studies have shown that there is a definite relationship between the carbon and iron oxide in the converter. This relationship is exhibited in Figure 14-7. Uniformity of product is influenced by control of iron-oxide content. After the carbon content has been lowered to

0.05 per cent, any further lowering of the carbon is accompanied by an increase in iron-oxide content. It is, therefore, apparent how important the determination of the end point becomes in insuring uniformity of product from blow to blow.

The quality of the pig iron furnished by the blast furnaces to an acid Bessemer shop will determine to a great extent the quality of the steel which can be produced. Iron of the correct chemical composition and temperature is required. For the best blowing, both from the standpoint of production and of quality, iron within the following ranges in composition is desired:

Element	Per Cent
Silicon	1.10 to 1.50
Manganese	0.40 to 0.70
Phosphorus	0.090 max.
Sulphur	0.030 max.

It is felt that for best blowing conditions a ratio of silicon to manganese of two or two and one-half to one should be maintained. The carbon content of the iron will range from 4.00 to 4.50 per cent, but chemical determination of this element in the iron generally is not made.

A typical charge for a 25-ton acid Bessemer converter is as follows:

Hot Metal (Bessemer).....	55,000 lbs.
Scrap	7,000 lbs.

With the above charge the blowing time will vary from eleven to fifteen minutes, depending upon the chemical composition of the iron and the condition of the bottom in respect to the number of blanked tuyeres. For the smaller, 10-ton converters, the time is shorter, averaging nine to eleven minutes.

Roll-scale additions are sometimes made in order to decrease blowing time. The roll scale, which is largely iron oxide, begins immediately to react with the silicon and manganese in the iron, and thus hastens their elimination. The scrap is added as a coolant. The amount required is estimated by the blower from his observations as to whether or not a satisfactory final temperature was obtained on the previous blow. The amount necessary to use will vary with the actual or physical temperature of the iron, as well as the potential chemical heat available in the iron, which in turn depends on its composition.

After the blower has made the decision that the blow should be terminated, the vessel is turned down and the blast turned off. Molten iron is added to the vessel at this time if it is desired to produce killed Bessemer steel, as described later under "Carbon Deoxidation." The ladle is positioned under the mouth of the converter to permit the blown metal to be poured into it. This operation is done slowly and carefully in order to retain as much slag in the vessel as practical. While the metal is pouring into the ladle, the recarburizers and de-oxidizers are added. When the vessel has been drained, the ladle is withdrawn and the vessel turned further from the vertical to permit the remaining slag to drop out into a slag pot mounted on a car below. The ladle is carried to the teeming platform, and the steel is teemed into the ingot molds. In the practice being described, each ladle is capable of containing all of the steel produced in two blowing operations; the content of a full ladle is referred to as a "heat."

STEEL-DISPOSAL EQUIPMENT

Ladles—Cup-shaped ladles constructed of steel plates are used to transfer the molten steel from the converter to a location where it can be teemed into the ingot molds. These ladles are generally similar to those de-

scribed and illustrated in Chapter 15 in connection with open-hearth practice. The ladles are lined with ladle brick and sealed with a thin clay slurry. To prevent the slag, which always floats on the steel in the ladle, from entering the mold and contaminating the ingot, the steel is teemed through a small hole, 2 inches in diameter, in the bottom of the ladle. For opening and closing this hole when moving from mold to mold, the ladle is equipped with a stopper which can be operated by the steel pourer on the teeming platform. This stopper consists of a steel rod, protected with fireclay sleeves, to the lower end of which is attached the stopperhead made of graphite, which fits snugly into the nozzle in the bottom of the ladle. The upper end of the stopper rod is fastened to a gooseneck which is keyed to a vertical sliding bar attached to the outside of the ladle. This bar is provided with a lever by which it may be raised or lowered, causing a like movement of the stopper. After the teeming of each heat the ladle is upended by an auxiliary hoist to dump the slag into the slag pot. At this time a wad of clay is inserted into the nozzle to guard against a leaking or running stopper when the ladle is refilled. The stopper rod is replaced after teeming so as to be ready for the next heat. The ladle is patched after teeming about eighteen heats. At this time the rim of the ladle is cleaned of adhering slag or steel, patched with clay and a new nozzle inserted in the bottom. Ladles require complete relining only after having teemed 50 to 60 heats or 100 to 120 blows.

Ingot Molds—The ingot molds into which the finished steel is teemed are made of cast iron. The standard mold used at the plant being discussed here as an example has a 24-inch x 27-inch average internal cross-section and is 81 inches high. The mold corners are rounded, the mold wall is corrugated, and the sides are tapered to facilitate stripping of the mold from the ingot. The molds are open at both ends and, when ready for teeming, rest big-end-down on heavy cast-iron plates called stools. A stool large enough to accommodate three molds is mounted on a small narrow-gage car or buggy. Buggies are constructed so that their sides form aprons which protect both the track on which the cars run and their own running gear from splattering by molten steel during teeming. The care of the molds is highly important, since dirty or defective molds will result in defects on the surface of the ingots, which in turn will be reflected in inferior surface of the rolled product. Good teeming practice resulting in clean, scab-free ingots, pays dividends in subsequent operations, since the cost involved in removing surface defects from the semifinished rolled product is thereby minimized.

The Stripper—As the name implies, this piece of equipment is designed to remove or strip the molds from the ingot after a sufficient time interval has elapsed after teeming to permit a substantial shell of solidified steel to have formed on all six surfaces of the ingot. It consists of a powerful overhead crane, from which is suspended a vertical arm with two jaws that engage lugs cast on the outside of the mold on either side near the top. Operating between the jaws is a ram or plunger, capable of exerting pressure on the top of the ingot. In stripping the ingot, the jaws engage the lugs and exert a powerful upward pull on the mold, while the ram, having been inserted through the open top of the mold, holds the ingot on the stool until the mold is loosened. The mold is then raised high enough to clear the ingot, and placed upon an empty car standing on an adjoining track. Illustrated descriptions of strippers are included in Chapter 15.

The older stripper installations are operated hydraulically, while the newer are powered electrically. The

electric strippers, since they are of the traveling type, possess a decided advantage over the older hydraulically operated machines, which are stationary. The most favorable location for the stripper is as close to the soaking-pit building as space requirements will permit. This is important, in that minimizing the time that elapses between stripping the molds from the ingots to completion of charging the ingots into the blooming-mill soaking pits, other things being equal, will result in better surface quality of the rolled product and reduce the amount of fuel required for reheating in the soaking pits.

CHEMISTRY OF THE ACID-BESSEMER BLOW

Some knowledge of the laws controlling chemical reactions is necessary for a clear understanding of the various reactions occurring in the acid Bessemer converter. The law of mass action states, in effect, that the rate or speed of a chemical reaction may be increased by increasing the active masses, or amounts, of one of the reacting substances; another law says that when chemical reactions take place without the addition of heat from an external source, those substances which have the greatest heats of formation, that is, those that give off the most energy during formation, will tend to form.

As previously stated the Bessemer blow usually is thought of as being divided into three parts, called the silicon blow, the carbon blow and the afterblow. Changes in chemical composition of the bath during progress of a 25-ton blow are shown diagrammatically in Figure 14-8.

The silicon blow commences as soon as the blast is let into the converter. The oxygen in the air unites directly with the iron to form iron oxide, which in turn combines with the silicon and manganese. These reactions and the net heat evolved can be shown by the following equations (unless otherwise stated, all heats of

FIG. 14-8. Changes in chemical composition of the metal in the bath of a 25-ton acid Bessemer converter during the progress of a blow.

reactions have been taken from "The Thermochemistry of the Chemical Substances," by F. Russell Bichowski and Frederick D. Rossini, published by Reinhold Publishing Corporation, New York, 1936):

With the oxidation of silicon and manganese, a slag is formed immediately by the combination of silica with the excess iron oxide and the manganese oxide, the reactions being illustrated generally as follows:

During this period of the blow, which lasts usually about four to five minutes, a short, stubby, transparent flame extends from the mouth of the converter. Pellets of molten iron and slag can be seen ejected by the blast. The converter gases evolved during this period are mainly nitrogen, with some carbon dioxide and traces of oxygen and hydrogen. The hydrogen results from the dissociation of water vapor in the blast.

The slag formed is intimately mixed with the metal as a result of the violent agitation of the bath, and, being a mixture of silicates, can either take on or give off some iron oxide. Thus, it also may help to oxidize the metalloids as long as they are present, or decoxidize the metal when the metalloids are absent. Toward the end of the period carbon may be oxidized either directly by the oxygen of the blast or by the dissolved iron oxide in the metal.

Such reactions account for the presence of both CO_2 and CO in converter gas during the first part of the blow. At the beginning of the blow CO is subject to reduction by both silicon and manganese, especially if the iron contains a high concentration of these elements.

As the temperature rises, the second period or carbon blow commences. The elapsed time for completion of this period is six to seven minutes. The reactions occurring now are as follows:

These reactions, in conjunction with reaction (6), rapidly burn out the remaining carbon. According to the law involving heats of formation, these reactions should not take place, but since one of the products is a gas and the net heat of reactions (1) and (10) is equal to the heat of formation of CO, they progress rapidly almost to completion under the conditions of blowing. Again, endothermic reactions may be reversed at high temperatures. This fact suggests the possibility that with "hot iron," that is, iron high in silicon, which is also initially at a very high temperature, it might be possible even to eliminate the carbon before the silicon and manganese could be oxidized, and the testimony of the older and more experienced operators of converters is to the effect that just such a result as this has often occurred when the conditions noted were present. Furthermore, in the elimination of the carbon, the law of mass action becomes prominent again, for with the elimination of the silicon and manganese, the active mass of the ferrous oxide rapidly increases until equilibrium is established with carbon. Comparatively little additional heat is generated in the bath during this period. The net heat generated is the difference between the heat of formation of FeO (115740 Btu) and that absorbed in reaction (10), (67430 Btu), or 48310 Btu which is the heat of formation of CO. The carbon reaction occurs concurrently with the phenomenon commonly spoken of as the boil. There is, during this period, very little, if any, iron oxidized above that required to eliminate the carbon, so each volume or molecule of oxygen in the blast will produce two volumes or molecules of CO. The converter gases, therefore, show a high content of CO, very little CO₂, and a marked decrease in N₂. But as the carbon is eliminated, the amount of oxygen in the metal increases, until the content of the former reaches a point between 0.01 and 0.02 per cent, when the oxygen content may increase rapidly without further oxidation of the carbon.

Phosphorus and Sulphur Control—In the acid process, the phosphorus and sulphur suffer no oxidation from the action of iron oxide. Assuming that the loss in weight in the bath from elimination of the metalloids, mechanical ejection by the blast and oxidation of iron and retention as iron oxide in the slag was 10 per cent, if an iron contained 0.030 per cent sulphur and 0.075 per cent phosphorus, the metal at the termination of the blow would contain approximately 0.033 per cent sulphur and 0.083 per cent phosphorus.

Iron ores with a low phosphorus content (less than 0.045 per cent) are required in the production of blast-furnace iron that can be converted into low-phosphorus steel by the acid Bessemer process without employing a separate dephosphorizing process.

Dephosphorization in the ladle has been used successfully for a number of years in the production of acid Bessemer steel with less than 0.050 per cent phosphorus. This is accomplished by adding a mixture of lime, iron oxides and flux, all in the solid state, to the blown metal as it flows into the ladle. Another method for phosphorus removal consists of the well-known duplex practice in which a tilting basic open-hearth furnace is employed. The technical possibilities of dephosphorization in the Bessemer process is a field for further investigation.

Sulphur in coke is also an important factor in Bessemer steel production as this element is not removed in the acid Bessemer process. If higher sulphur coke is used in Bessemer iron production, it is necessary either to remove sufficient sulphur in the blast furnace or resort to other treatments. In the blast furnace, limestone in the charge is adjusted with the burden for sulphur removal. Ladle treatments have been developed

in which fused sodium carbonate or sodium hydroxide has been used successfully, particularly with cupola iron. In the duplex process, sulphur may be removed to some extent in the basic open-hearth furnace. In Europe, a certain amount of sulphur is removed in the basic Bessemer process.

PROCESS AND QUALITY CONTROL

End Point Evaluation—Although visual characteristics continue to be the most widely used means of controlling the Bessemer blow and determining the end-point characteristics, several instruments have been investigated in an attempt to obtain better control. The spectroscope, one of the first instruments investigated, has been used with reasonable success. The amount of natural light and other conditions in the Bessemer plant may interfere with and limit its applications. It is necessary, depending on the grade of steel being produced, to select a time interval after changes in the spectrum are observed in order to turn down the vessel at the proper carbon content.

Automatic recording of the radiation characteristics of the flame as measured by a photocell also has been used to aid in control of the Bessemer blow. As the flame drops at the end of a blow, the curve drawn by the recorder indicates an arrest which is taken as the end point. Each type of steel requires a specific afterblow, measured in seconds, which is determined by statistical studies of variations in yield and quality with time of afterblow, beyond this end point.

One of the most important features of end-point control is the elimination of overblowing which results in the absorption of excessive amounts of oxygen and nitrogen. This not only affects the efficiency of deoxidation, but also influences behavior of the product during processing in the rolling mills.

Temperature Control—The production of steel by the converter process requires careful temperature control in order to insure satisfactory practice. If the finished steel is too low in temperature, ladle skulling and pouring nozzle difficulties will be encountered which are undesirable from the viewpoint of steel quality. Steel with a high temperature not only contains excessive quantities of nitrogen and oxygen, but also is unsatisfactory in other respects. The Bessemer blower is, therefore, confronted with the problem of producing steel at a satisfactory temperature which can be determined conveniently at the present time only with an optical pyrometer as the blown metal is poured into the ladle or during teeming. Many attempts have been made to develop a satisfactory device to measure temperature of the molten charge during the Bessemer blow, but a satisfactory technique has not been developed. The blower still must continue to depend upon the characteristics of the flame.

A photronic cell located in the wind-box has been investigated and the possibilities of making accurate temperature determinations by this method are promising, but additional experimental work will be required to develop a satisfactory technique.

Chemical composition of the iron is a fundamental consideration with respect to temperature control, particularly with regard to silicon. The oxidation of silicon is an exothermic chemical reaction and data showing the actual silicon content in the iron should be available to the blower. If the silicon content is high, cold metal (scrap) or pig iron may be added to the vessel to eliminate the necessity for steaming. If the silicon content is too low, it may be necessary to side blow in order to increase the temperature of the metal. During the blow, if the temperature is excessive, all of the silicon may

not be removed before carbon oxidation predominates.

A cold ladle or vessel and the amount of ferroalloy addition at the end of the blow are among the factors which must be considered by the blower in producing steel with a satisfactory temperature. The blower, therefore, must take into consideration the many variables which affect temperature and, by judging character of the flame, produce a satisfactory quality steel. The accurate determination of temperature during the blow with a radiation instrument, consequently, would be of considerable assistance in the economic production of Bessemer steel.

Oxygen-Enriched Blast—Extensive investigations of the use of an oxygen-enriched blast have been carried out with the following results:

- (1) Shorter blowing time resulted.
- (2) Greater utilization of cold iron and scrap was achieved.
- (3) With a blast containing about 30 per cent oxygen, the bottom and vessel linings were not abnormally worn in a limited number of heats.
- (4) Steel quality was similar to regular Bessemer heats.
- (5) Flame characteristics were readily distinguishable by blowers and satisfactory teeming temperatures were obtained.

Blowing Time and Quality—One of the important economic factors in the production of Bessemer steel is that a blow usually lasts for a period of only 10 to 15 minutes. However, the time required to make a certain quantity of steel depends on size of the vessel, and converters in this country are relatively small. Due to the fact that the time required to make an acid Bessemer blow is relatively short, the problem of controlling quality of the product differs somewhat from open-hearth practice. Speed of the operation is so rapid that the necessity for certain control measures differs from those required by the open-hearth melter. The Bessemer process, to a marked degree, is automatic in its operation.

The composition of the steel cannot be regulated satisfactorily by stopping the blow at an intermediate point due to the speed of reactions and other conditions. It is possible to blow a Bessemer heat to any selected carbon level, but a product more uniform in chemical composition is obtained by blowing to the drop of the flame and adding carbon and manganese as required. High-carbon blown metal is sometimes produced in the duplex proc-

ess as further refining and adjustment in chemical composition are made in the open-hearth furnace. At the first indication of a drop of the flame and other changes in appearance of the flame, the converter may be turned down "young," and the carbon content will be approximately 0.10 per cent. However, most of the acid Bessemer steel is blown "full" to insure uniform composition. The vessel is turned down as height of the flame continues to decrease and certain changes in appearance are observed. Full-blown heats contain approximately 0.04 per cent carbon. If the manganese content of the metal at the beginning of the blow is too high, a fluid slag which contributes to "slopping" is produced. Therefore, the ratio of silicon to manganese must be controlled. Silicon already has been described as a source of heat and therefore an important factor in temperature control during the blow.

DEOXIDATION OF ACID BESSEMER STEEL

General—In the Bessemer process, characteristics of the flame at the end of the blow and the deoxidation practice employed are fundamental factors which control quality of the product. The additions required to produce various grades of acid Bessemer steel are incorporated in the deoxidation practice and may be added to the vessel, ladle, or mold.

In the deoxidation of acid Bessemer steel, the oxygen content of the blown metal is one of the significant factors involved. The iron oxide content is also related to the nitrogen content in that both are increased by higher temperatures and overblowing. In the production of killed acid Bessemer steels, the deoxidation practice also must take into consideration the fixation of nitrogen. Therefore, for proper deoxidation, it is essential to control carefully the temperature and end point of the Bessemer blow.

Rimmed and capped acid Bessemer steels usually are blown fully and finished with a low carbon content. These steels are not completely deoxidized so that a strong evolution of gas occurs during solidification in the mold. Sufficient deoxidizer may be added, either in the ladle or mold, to control action in the mold (Table 14—III). In capped steels, the period of gas evolution in the mold is further controlled by using a steel cap which chills and solidifies the top of the ingot. Steel of this type usually contains about 0.07 per cent carbon, 0.45 per cent manganese, 0.08 per cent phosphorus, 0.025 per cent sulphur and 0.005 per cent silicon. In the manufacture of killed acid Bessemer steel, strong deoxidizers, includ-

Table 14—III. Typical Compositions of Deoxidizers (Per Cent)

	Fe	C	Mn	S	P	Si	Ash
Ferromanganese	11.95	6.50	80.40	Trace	0.160	1.00

Aluminum	2.24	90.19	4.14	0.66	2.28		

ing carbon, ferrosilicon and aluminum are added to the molten steel at the end of the blow. Ingots with a dense, homogenous structure, relatively free from porosity or blowholes, are produced from killed steel. Steel of this type may contain 0.10 per cent or more carbon, 0.35–1.25 per cent manganese, 0.10–0.30 per cent silicon, 0.08 per cent phosphorus and 0.025 per cent sulphur. Alloys also may be added if desired. The factors responsible for the superior quality of deoxidized as compared with rimmed or capped acid Bessemer steel do not depend entirely on the fact that a killed steel is involved, but more precisely, are related to the method of killing the steel.

Carbon Deoxidation—The oxygen content of rimmed or capped acid Bessemer steels is high and must, to a certain degree, be evaluated by behavior of metal in the mold. These steels are generally low in carbon, and carbon deoxidation is not an important factor in the production of "open" steels.

The carbon content of killed acid Bessemer steel varies from 0.10 per cent to any higher level desired, depending upon the grade of steel. A sufficient amount of deoxidizer is added to produce a steel which has no action in the mold. In order to meet carbon requirements and properly deoxidize the steel, molten blast-furnace iron containing about 4 per cent carbon is added to the vessel at the end of the blow. After the addition of hot metal, a reaction takes place for several minutes in the vessel which results in the formation of carbon monoxide gas. This is similar in some respects to "blocking" an open-hearth heat (described in Chapter 15), except that the mixing of blown metal and hot metal is almost instantaneous. The carbon monoxide burns at the mouth of the converter. Removal of oxygen as a gas not only deoxidizes the steel but removes oxygen immediately instead of forming a solid metallic inclusion which must rise to the surface of the steel. Steel made by this process is distinctly different from regular acid Bessemer steel. The steel contains fewer non-metallic inclusions than if silicon or aluminum had been added before the carbon reaction.

In the use of hot metal for deoxidation of acid Bessemer steel, provisions must be made for accurate weighing of the addition. Other means may be used for carbon deoxidation in which solid materials are added, but the simplest and most thorough method at the time this is written is the use of hot metal.

Manganese and Silicon Additions—In the manufacture of killed acid Bessemer steels manganese and silicon may be added after carbon deoxidation either to the vessel or ladle in sufficient quantity to provide the amount desired in the finished steel. Additions to the

vessel are preferred and are accomplished by the use of a chute, as shown in Figure 14–9. Usually, 75 per cent ferromanganese and 50 per cent ferrosilicon are employed. Special types of deoxidizers containing silicon and/or manganese with aluminum have been used successfully. In the manufacture of rimmed or capped acid Bessemer steels, silicon is seldom used, and manganese is added to the ladle for fixation of sulphur and to improve rolling characteristics. The efficiencies of the various additions are similar to open hearth practice at the same carbon level.

Although aluminum is added to steel primarily for deoxidation purposes, it also is used for nitrogen fixation in killed acid Bessemer steels. The fixation of nitrogen with aluminum or other elements imparts superior toughness and improved resistance to notch sensitivity. The proper use of aluminum or its equivalent is essential in the production of a satisfactory killed acid Bessemer steel.

ECONOMIC CONSIDERATIONS

Investment Costs—The cost of building an acid Bessemer plant is appreciably less than an open-hearth plant of equivalent capacity and the difference in cost depends, to some extent, upon the size of individual units. However, in the operation of an acid Bessemer plant, greater blast-furnace and by-product coke capacity is required as only a small amount of scrap is used in the process. Therefore, the investment in blast-furnace and by-product coke facilities for the acid Bessemer plant would be greater than for an open-hearth plant and must be considered as part of the investment costs. This probably was a factor which, to some extent, was responsible for the shift from acid Bessemer to basic open-hearth steel production during the years between about 1910 and the present.

With proper facilities in an integrated plant, consisting of acid Bessemer converters and tilting or stationary basic open-hearth furnaces, the cost of producing Bessemer ingots over a period of years should be less than open-hearth ingots. When a shortage of scrap exists and the price is high, acid Bessemer facilities not only have an economic advantage, but are in a better position to meet market demands for steel products. This latter feature is of considerable importance in time of a national emergency.

Scrap Market Conditions—The ratio of acid Bessemer to basic open-hearth steel production is influenced by the availability of steel scrap. The Bessemer process uses about 10 per cent scrap. The duplex open-hearth process utilizes very little scrap while the stationary open-hearth process ordinarily employs 35 per cent to 60 per cent. Although the quantity of scrap used in the Bessemer process is small, this quantity may be increased appreciably in the future to approximately 25 per cent by oxygen-enrichment of the blast. Further, the use of scrap in the blast furnace may be considered in the Bessemer situation.

The Bessemer process produces more scrap than it consumes. The crop ends in the blooming mill alone produce about 15 per cent, and additional scrap is produced in further processing of the material. The stationary open-hearth process produces a similar amount of scrap, but constantly uses more than it produces. The deficit is supplied by scrap originating from the Bessemer process and from sources outside the plant.

The Bessemer process has certain economic advantages when scrap is scarce and costly, but there are periods in our economy when scrap is plentiful and cheap. Therefore, the economic pressure which exists over a period of years will be a controlling factor which

FIG. 14–9. Diagram illustrating the use of a crane-operated chute for making additions of solid materials to a Bessemer converter.

influences the acid Bessemer steelmaking production of the nation.

Metal Losses—Metallic yield in the acid Bessemer process is comparable with stationary open-hearth practices and is influenced by metalloid losses, oxidation of iron, slopping and other operation characteristics. Depending upon facilities and operating conditions, the performance of acid Bessemer plants in terms of metal yield has been similar to that of open-hearth plants.

Possible Future Trends—The future design of converters probably will be directed to the construction of vessels with a larger capacity in order to reduce the cost of acid Bessemer steel. A number of large bottom-blown (basic) converters with capacities exceeding 50 tons were in operation in Germany during World War II. At present, the size of a heat may be increased by pouring several acid Bessemer blows in one ladle and this practice has some of the advantages which are achieved in open-hearth practice with larger furnace

capacities. In order for rimmed or capped converter steel to have properties similar to open-hearth steel, it is not only necessary to reduce the nitrogen content, but also the phosphorus content of the finished steel. In the manufacture of seamless pipe, the phosphorus content of killed converter steel imparts to the steel strength properties which are achieved in open-hearth steel only at higher levels of carbon, or by deliberate increase of phosphorus and/or nitrogen content.

Changes in converter design require thorough evaluation with respect to operating characteristics. The problems encountered in open-hearth design are of an entirely different nature, and if a similar effort had been directed in this country to converter design and practice, considerably more progress would have resulted. Present trends in the use of oxygen and compressed air in the bath of open-hearth furnaces indicate clearly the future possibilities of a more widespread use of the fundamental principles of the pneumatic processes.

SECTION 3

THE BASIC BESSEMER OR THOMAS PROCESS

Historical—The bottom-blown basic pneumatic process known by the several names of the **Thomas, Thomas-Gilchrist** or **basic Bessemer process**, was patented in 1879 by Sidney G. Thomas in England. The process (never adopted in the United States) developed much more rapidly on the Continent than in Great Britain and, in 1890, Continental production was over 2 million tons as compared with 400,000 tons made in Great Britain.

The simultaneous development of the basic open-hearth process resulted in a decline of production of steel by the bottom-blown basic pneumatic process in Europe and, by 1904, production of basic open-hearth steel there exceeded that of basic pneumatic steel. From 1910 on, the bottom-blown basic pneumatic process declined continuously until World War II.

Composition of Pig Iron for Basic Process—The bottom-blown basic pneumatic process requires the use of a basic lining in the converter, and the use of lime or limestone as a slag-making material. The basic slag makes the process capable of removing phosphorus (and sulphur) from the blast-furnace iron. Thus, iron can be produced from iron ores of lower grade, using lower-grade coke as fuel, than would be permissible in production of iron for the acid Bessemer process which cannot remove phosphorus or sulphur and requires irons with a low content of these two elements.

A typical blast-furnace iron for the bottom-blown basic pneumatic process contains from 1.4 to 2.0 per cent of phosphorus and approximately 0.5 per cent of silicon. Iron ore and other raw materials of the type required to produce iron of this composition in the blast furnace, or to give a molten product of this composition when pig iron is melted in the cupola, have been and still are available abroad in rather large quantities.

Since some phosphorus and sulphur are removed in the bottom-blown basic pneumatic process, the chemical composition and properties of steels produced by this method more closely approach the composition and properties of basic open-hearth steels of similar grade than do comparable steels made by the acid Bessemer process. However, the oxygen content of the bottom-blown basic pneumatic steels is generally higher and the nitrogen content is definitely higher than that of basic open-hearth steel. For these reasons, the properties of steels made by the basic Bessemer (Thomas)

process, while more similar to basic open-hearth steels than are acid Bessemer steels, are still inadequate for certain applications because of their higher strength, lower ductility and susceptibility to strain aging.

PRINCIPAL FACILITIES

The equipment for the bottom-blown basic pneumatic process is very similar to that described for the acid Bessemer process in Section 2. Consequently, the following description will mention largely differences between the types of equipment used for the two processes. A typical Thomas steel plant has six 25-ton vessels which can produce about 120 tons of steel per hour or 3000 tons per day.

Mixer—Hot-metal mixers for the Thomas plants are of the same general size and type as those already described in connection with acid Bessemer steel plants. Some so-called "active" mixers with regenerators are used to keep the iron hotter, and through the addition of lime some refining also is carried out prior to charging the metal in the converters. Many mixers are lined with magnesite brick rather than with siliceous refractories.

Blowing Equipment—There are no marked differences in blowing equipment for the bottom-blown basic pneumatic process from that already described for the acid Bessemer process. The normal air-blast pressure in the basic process is 35 pounds per square inch, which is somewhat higher than that employed for the acid Bessemer process in the United States.

THE CONVERTER OR VESSEL

The size of bottom-blown basic converters varies from 25 tons to 60 tons capacity. The design of vessels is similar to that of the acid Bessemer converters used in America. A large number of basic vessels are concentric rather than eccentric, in relation to the position of the opening in the nose. To conserve heat, the nose opening in some basic vessels is quite small. Further, the bottom design and the lining, of course, are different. Almost all of the bottom-blown basic pneumatic converters are lined at present with a mixture of tar and burned dolomite rammed into place in the vessel.

Bottom Design—The bottom of the basic converters used in most plants contains about 200 holes, each $\frac{1}{2}$ inch in diameter. Separate tuyere brick are not used in

these bottoms; instead the holes are formed by ramming the refractory bottom material around wooden plugs. The bottom is then heated in an intermittent-type oven for a period of six days, after which the wooden plugs, which have been converted to soft charcoal, are drilled out. Bottoms with tangentially inclined holes have been tried over a long period but have not been proven to have any appreciable effect in improving operations.

Lining and Bottom Life—The lower part of the lining of a bottom-blown basic converter requires replacement after about 200 blows, on the average. The remainder of the lining, with the exception of the bottom, withstands about 400 blows. Bottom life averages about 40 blows. Dolomite consumption has been reported as about 22 pounds per ton of steel produced.

SEQUENCE OF OPERATIONS

The steps in making a heat of steel in a bottom-blown basic converter vary largely because of recent innovations and changes introduced in an effort to consistently produce steels of low nitrogen content. The general sequence in a typical British plant is as follows: the blast-furnace iron is partially desulphurized between the blast furnace and the mixer or between the mixer and the converter by additions of soda ash. Slag produced by the desulphurization operation is carefully skimmed off before charging the iron into the converter. With the vessel in the horizontal position, the necessary burnt lime (averaging 300 pounds per ton of iron) is added by an overhead chute. The vessel is then turned down past the horizontal position and a weighed molten iron charge is added. Blowing is started with a blast pressure of 30 pounds per square inch. The time of addition of scrap, required to control the temperature of the blow, varies with the type of scrap available. With bloom-end scrap the addition is made two or three minutes before the drop of the flame but, with heavy ingot scrap, the addition is made early in the blow to allow for the complete melting of the scrap.

The total duration of the blow depends upon time of additions and other operating factors. The end point is determined by visual inspection of the flame, confirmed by the blower's judgment of a fractured sample of steel taken from the vessel. After blowing is completed, most of the slag is removed by tilting the vessel, following which the necessary amount of ferromanganese is added to the steel in hot lump form. The residual slag is retained in the vessel by the formation of a lime dam in the mouth of the vessel while the steel is poured into the ladle held underneath the vessel by the casting car. For a 40-ton converter, the total duration of blow is 15 to 16 minutes, including an after blow of 3 to 5 minutes. It should be noted that the after blow in the basic process is relatively long as compared with the acid Bessemer process; this is necessary to accomplish removal of phosphorus from the bath. The end point of a basic Bessemer blow is very similar to that of the acid Bessemer process, but occurs somewhat earlier in the blow because of the lower silicon content of the iron used in the basic process which results in a shorter silicon blow. A 40-ton vessel has been reported to use about 12,000 cubic feet of air per ton of steel produced.

CHEMISTRY OF THE THOMAS PROCESS

Oxidation Reactions—The major chemical differences between the bottom-blown acid and basic pneumatic processes lies in the chemical reactions involving removal of phosphorus (and to some extent, sulphur) from the iron. The effective removal of these elements depends almost entirely on slag-metal reactions which are almost absent in the acid Bessemer process. Oxida-

tion of carbon, manganese and silicon occurs in essentially the same manner as was described for the acid Bessemer process.

The removal of phosphorus from the metal involves first its oxidation to phosphoric acid anhydride (P_2O_5) which then combines with lime (CaO) in the slag to form the chemical compound ($4CaO \cdot P_2O_5$). The removal of sulphur depends upon the migration of ferrous sulphide (FeS) into the slag where it reacts with lime (CaO) to form calcium sulphide (CaS).

The removal of both phosphorus and sulphur in the basic pneumatic process depends upon the concentration of lime in the slag; however, removal of phosphorus is favored by a high content of iron oxide in the slag and oxygen in the metal, while sulphur removal is favored by the reverse conditions. Thus, only a small amount of sulphur is removed in the basic pneumatic process unless slags with a high lime content are formed. Further, because of the nature of the dephosphorization reaction, it occurs largely after the removal of the majority of the carbon, in the after-blow period. Figure 14-10 illustrates the course of the oxidizing reactions

FIG. 14-10. Changes in chemical composition of the metal in the bath of a bottom-blown basic-lined pneumatic converter during a typical Thomas blow (after Carney).

during a typical Thomas blow. As in most basic steel-making processes, an undesired reversion of manganese and phosphorus from slag to metal is more probable if high finishing temperatures are attained.

Thermal Requirements—In the bottom-blown basic pneumatic process, lime is added with the hot metal. This added cold material, as well as the greater slag volume produced, requires additional heat as compared with the acid process. In the basic pneumatic process, iron of higher silicon content cannot be used to obtain this additional heat, since the more silicon the iron contains, the more lime will be required to flux the oxidized silicon (silica, SiO_2) both to prevent the silica from attacking the lining and to keep the slag basic enough for effective phosphorus and sulphur removal. The higher the silicon content of the iron, the greater will be the slag volume produced. Fortunately, in the bottom-blown basic converter, a portion of the additional heat required is obtained from the oxidation of phosphorus in the iron. For this reason, a proper thermal balance in the bottom-blown basic converter makes the relative percentages of silicon and phosphorus in the iron critical. A typical blast-furnace iron for use in the Thomas

process at present contains 0.2 to 0.4 per cent silicon, 0.6 to 1.0 per cent manganese, 1.5 to 2.0 per cent phosphorus and 0.03 to 0.05 per cent sulphur. The phosphoric acid anhydride (P_2O_5) content of the final slag produced in bottom-blowing iron of the above composition in a basic converter, using 300 pounds of lime per ton of steel, is about 16 to 18 per cent, with a slag volume of about 20 to 22 per cent. Slags of this composition make desirable fertilizers and they are processed and sold for this purpose, thus aiding the economics of the process.

Temperature Control—During a bottom-blown basic converter blow, the temperature normally rises during the oxidation of silicon, remains fairly constant during the carbon blow, and rises rapidly during the after blow. In some respects control of temperature in the bottom-blown basic converter is more important than in the acid Bessemer vessel because of the need for effective control of phosphorus content of the finished steel. The methods used for temperature control during a blow are very similar for both the basic and acid processes. The most important factors relating to temperatures in the vessel are the as-charged temperature and composition of the iron being blown and the blowing time. Common methods for controlling temperature during blowing are the use of side blowing to increase temperature and the use of steam and scrap to decrease temperature. The photocell and immersion thermocouples have been used with some success in quite a few plants for controlling the end point and for accurately recording the final bath temperature. The main reason for this closer control of temperature is the concern over residual nitrogen and the desire to produce low-nitrogen steels. Residual nitrogen contents are markedly affected by the bath temperature.

Deoxidation Reactions—There are no major differences in the deoxidation reactions between the bottom-blown acid and basic pneumatic processes. A fair number of heats produced in the bottom-blown basic converter in Europe are fully killed. In the United States considerable tonnages of killed acid Bessemer steel are produced. Deoxidation with aluminum is practiced more generally abroad than in the United States. Much of the deoxidation with aluminum in Europe is accomplished by ladle additions compared with mold additions in this country.

Nitrogen Control—Since bottom-blown basic pneumatic steels have sulphur and phosphorus contents similar to or slightly higher than those of basic open-hearth steels, many attempts have been made to develop practices that would make it possible to reduce the nitrogen content of these steels to levels approaching that normally attained in basic open-hearth steels (0.003 to 0.005 per cent nitrogen). Some of the factors which influence the nitrogen content of the pneumatic steels were covered in Section 2 where the acid Bessemer process was discussed. In general, the following items have been found to be important in the commercial production of low-nitrogen bottom-blown pneumatic steels:

- (a) The blow must be worked at a low temperature.
- (b) A shallow metal bath is desirable to limit time of contact between gases and metal.
- (c) High nitrogen content of the blowing gases, especially during the latter part of the blow, should be lowered when possible by use of oxygen-enriched air, mixtures of oxygen and steam, mixtures of oxygen and CO_2 , or other means.

(d) Pressure of the blowing gases should be kept as low as possible, compatible with reasonable blowing time.

(e) Irregularity in blast-furnace operations is believed to promote higher nitrogen content of pig iron, which complicates the production of low-nitrogen steels in the basic bottom-blown converter.

The most frequently used methods for producing low-nitrogen steels in the basic bottom-blown converter have been based upon shortening the after blow and also upon cooling the bath at this point. In one method, this is accomplished by adding ore or roll scale (up to 2.5 per cent) a little before the carbon flame drops to effect oxidation without the introduction of nitrogen while simultaneously cooling the bath. This method may contribute to difficulties arising from low finishing temperatures that cause ladle-skull formation and pouring difficulties due to cold steel.

A second method obviates some of the pouring difficulties while speeding up the process. Best suited to 50 to 60-ton converters, this method consists of double-blowing the metal. Half of the total iron and all of the lime is charged first and blown down to about 0.1 per cent of phosphorus. The shallow bath permits high-pressure blowing without excessive spitting. The balance of the charge is then added and blowing continued, again at high pressures made possible by the diluting effect of the first-blown metal. The total blowing time can be reduced from 16 to 17 minutes to 11 to 12 minutes by this method which is said to increase average size of charge, increase yield and still produce steel lower in phosphorus and nitrogen content than steels produced by ordinary blowing.

A third means for reducing the nitrogen content of Thomas steel involves a modification of the converter so that the blast is introduced through the side of the vessel at a point intermediate between the bottom of the vessel and the level of the bath. The aim of this modification is to reduce the length of travel of the blast through the bath and thus minimize the time for absorption of nitrogen without sacrificing the other characteristics of bottom blowing. It has been observed that nitrogen absorption in acid surface blowing practices is quite low. Consequently, it has been hypothesized that the degree of nitrogen absorption, other things being equal, would be related to the length of travel or time of contact of the air blast with the metal. Modification of the Thomas converter in this manner does not influence the remaining operations and the typical course of the refining remains the same as that shown in Figure 14—10, with the exception that lower nitrogen values are achieved.

Considerable quantities of low-nitrogen steel have been produced by the basic bottom-blown pneumatic process for wire, ship plates, deep-drawing steels, high-carbon high-tensile steels, and killed steels for various purposes. These products require less deoxidation than the material produced by ordinary blowing, and their properties are quite similar to basic open-hearth steels of comparable grades.

Control of End Point—The discussion of the control of end point in Section 2 dealing with the acid Bessemer process applies equally well to the basic bottom-blown process. The spectroscope is used very little in Europe, the most common methods of control being visual observation of the flame by the blower, the use of fractured samples, and the use of the photocell.

SECTION 4

THE SURFACE-SIDE-BLOWN ACID PROCESS

The side-blown acid pneumatic converter is sometimes referred to as a surface-blown converter, or as the Tropenas converter. The chemical reactions which occur in the side-blown acid converter are similar to those occurring in the bottom-blown acid converter; the major difference is the mechanism by which these reactions take place. There have been numerous variations of design of converters employing the side-blowing technique, but all are characterized by having all of the tuyeres above the liquid level of the bath and entering through the side of the vessel.

In bottom-blown converters, the exposure of some of the tuyeres above the liquid level by tilting the converter while blowing increases the temperature inside the vessel, as discussed in Section 2. With all of its tuyeres above liquid level in normal operating position of the vessel, the side-blown acid converter can produce much hotter steel from a similar iron charge than can the bottom-blown acid converter. Temperatures in excess of 3200 °F (1760 °C) can be attained if desired, blowing cupola-melted iron in lots as small as 1000 pounds. Its ability to process small heats at high temperatures and at frequent intervals that can keep up with pouring-floor schedules makes the side-blown acid converter useful to foundries making steel castings.

The quality of ore, coke and other raw materials required to produce iron for the side-blown acid process is similar to that required for the bottom-blown acid process; however, because additional heat is obtained from the oxidation of carbon to carbon monoxide inside the vessel, the silicon content of the iron can be somewhat lower.

The Converter and Its Auxiliaries—Since most side-blown vessels are used in foundries at present, hot-metal mixers are seldom available to provide a source of liquid iron for side-blown acid converters. Mixers, when used, are quite small. Generally, the cupola is employed to melt solid pigs of iron of the proper composition; the cupola can be tapped frequently to supply the side-blown converter with liquid iron as needed.

FIG. 14—11. Sectional drawing of a typical side-blown acid converter. While the cross-section of the interior of the type shown is D shaped, many side-blown acid converters are circular in interior cross-section.

Side blowing requires lower blast pressures and smaller volumes of air than bottom blowing; blast pressures between 4 and 10 pounds per square inch are common.

The majority of side-blown acid converters are of one-half to two-ton capacity, although a few larger vessels have been built. Figure 14—11 is a sectional drawing of a typical side-blown acid converter. The refractories used for lining are similar to those used in bottom-blown converters.

Sequence of Operations—While the chemical reactions of the side-blown acid process proceed at a slightly different rate and in a different manner than those of the bottom-blown process, the physical steps in making heats by both processes are quite similar. The end point is observed from the drop of the flame. The length of the flame is shorter than that for the bottom-blown vessel. In the acid processes, the addition of controlled amounts of ferrosilicon to the vessel during blowing to make available more potential heat units is practiced much more frequently in side blowing than in bottom blowing.

Oxidation Reactions—While the chemical reactions which occur in the side-blown acid pneumatic process are similar to those in the other pneumatic processes, the mechanisms by which these reactions take place are somewhat different. The elimination of carbon, manganese and silicon in the side-blown acid process may be considered as taking place in three stages:

(1) The blast of air impinges on the surface of the bath of molten iron and immediately forms a layer of iron oxide. Some silicon and manganese oxides are formed during this stage, but the initial slag consists mainly of iron oxide.

(2) From the time when the metal is completely covered with slag, the oxidation of manganese and silicon is accelerated; the reactions are considered to be between the slag and the metal and not between air and metal as in the bottom-blown converter. During this period, there is a rapid rise in temperature of the bath because of the exothermic reactions involved. Ferrosilicon can be, and is, added before and during the blow, these additions being governed by vessel temperature, metal composition, and metal temperature. Larger additions of ferrosilicon are made when low-carbon metal (2 to 3 per cent carbon) is being blown. The higher silicon content of the bath provided by ferrosilicon additions functions as a kindling agent, and during the oxidation of silicon the temperature of the bath increases to about 2640 °F; at this temperature the silicon content of the bath is about 0.6 to 0.7 per cent.

(3) After the silicon content has been lowered to the above figure, the oxidation of carbon increases to a very rapid rate and the temperature of the bath increases considerably. The oxidation of carbon in the metal by FeO or other oxides in the slag produces carbon monoxide, which may burn to carbon dioxide in the presence of excess air within the vessel. This represents an essential difference between the side-blown and bottom-blown processes, insofar as considerably more heat per unit of carbon in the bath is generated in side-blown practice.

Toward the end of the carbon-oxidation stage, when the bath is attaining its final temperature of 3000 to 3100 °F, other reactions take place which result in the

reduction of SiO_2 and MnO by carbon. It has been established that, under the above conditions of slag and metal, the silicon content of the final metal after the additions of deoxidizing agents and alloys is always greater than can be accounted for by the silicon content of the additions, thus indicating some reduction of silica in the slag to silicon which enters the metal.

Temperature Control—The methods of temperature control used in side blowing are quite similar to those already discussed for bottom blowing. Ferrosilicon is frequently added to the cupola iron during blowing to raise the temperature. Accurate temperature control is vital to the production of quality steel, but apparently is not so critical in regard to the final nitrogen content of the steel as it is with bottom blowing. Little trouble with excess nitrogen absorption in the side-blowing process has been reported, even with steel temperatures up to 3100°F .

Deoxidation Reactions—Deoxidation reactions of side-blown acid pneumatic steels are similar to those in finishing bottom-blown acid heats. However, since the majority of the side-blown steel is used for castings, these steels are fully killed, using as much as four pounds of aluminum per ton of steel.

Nitrogen Control—A major part of the side-blown acid steels are produced with a relatively low nitrogen content (0.003 to 0.008 per cent). Because of the short time of contact of gases and metal, nitrogen control is not as difficult in side blowing as it is in bottom blowing. The use of low finishing temperatures or ore additions is not practiced to any great extent. However, some work has been done on the use of oxygen and oxygen-enriched air for blowing to reduce the nitrogen content to even lower levels (0.002 to 0.003 per cent). These latter practices are not common at present.

Control of the End Point—End-point control in the side-blown acid pneumatic process is very similar to the control exercised in the bottom-blown processes, even though the size of the flame is quite different. The end point is usually determined visually by the drop of the flame.

Oxygen and Oxygen-Enriched Air for Blast—Recent experiments using oxygen-enriched air and 98 to 100 per cent oxygen for blowing in the side-blown acid process showed that blowing time was shortened and the final bath temperature was increased. Blowing losses increased after the proportion of oxygen in the blast exceeded 30 to 35 per cent.

SECTION 5

THE OXYGEN-BLOWN BASIC STEELMAKING PROCESSES

Variations of the pneumatic steelmaking processes which employ oxygen of high purity blown onto the surface of the bath in a basic-lined vessel may become of increasing importance in the future. Oxygen at high or relatively low pressures has been employed, blown through the mouth of the vessel vertically or at an angle to the surface of the bath.

One variation is the so-called Linz-Donawitz or L-D process, in which oxygen of high purity is blown at high velocity onto the surface of the bath in a basic-lined vessel by a vertical pipe or lance inserted through the mouth of a vessel. The name for this top-blown basic process is derived from the towns in Austria where these practices have been adopted on a commercial scale. At the present time, no commercial production of steel by top-blowing in an acid vessel is being conducted although the principle has been employed for desiliconizing pig iron to be used in the basic open-hearth process. The top-blown basic steelmaking process was developed in Austria to employ pig iron produced from local ores that are high in manganese and low in phosphorus; such iron is not entirely suitable for either the acid or basic bottom-blown pneumatic processes. Lack of a sufficient supply of scrap in Austria made it desirable to employ a steelmaking process requiring large percentages of hot metal as the prime source of metallics. Also, the majority of the steel produced was intended for applications requiring steels low in sulphur, phosphorus and nitrogen.

Mixers and Blowing Equipment—Conventional mixers are used in this process. At one plant, two 500-ton mixers service three 30-ton vessels; at another, one 1000-ton mixer services two 30-ton vessels. Since oxygen rather than air is used in the top-blown basic process, equipment capable of supplying high-purity oxygen under pressure is used in place of the normal air-blowing equipment. Oxygen is normally stored in tanks under a pressure of 375 pounds per square inch to allow for the intermittent operation of the vessels.

The Vessel—The design of the top-blown basic vessel is the simplest of all steelmaking furnaces. There are no tuyeres. Oxygen is supplied by a single water-cooled lance with a copper nozzle, suspended vertically so that

it can be raised and lowered through the mouth of the vessel to within the desired distance from the metal bath. The vessel itself, shown schematically in Figure 14—12, is refractory-lined and ladle-shaped with either a concentric or eccentric nose. The bottom of the vessel may or may not be detachable; both types are currently being used. The lining consists of a single course of magnesite brick covered with a rammed layer of tar and magnesite. Large bricks made from tar and dolomite have also been used. The lining must be almost completely replaced after 200 or more heats. Refractory consumption has been reported as between 20 and 30 pounds per ton of steel ingots. The vessels are supported on conventional trunnions that permit tilting for charge-

FIG. 14—12. Types of vessel used when blowing oxygen vertically downwards on to the metal through a water-cooled lance.

ing and pouring. The tops of the vessels have hoods for dust collection.

Sequence of Operations—A normal practice is to first charge scrap and hot metal through the nose of the tilted vessel. The vessel is then righted to vertical position and the oxygen lance is lowered from above into the nose of the vessel and to within 25 to 40 inches of the bath. The oxygen is turned on and limestone is charged from an overhead chute. Reactions occur immediately. During the process, lime and scrap are added as required for slag making and temperature control. The end point is indicated by the disappearance of the flame playing at the mouth of the vessel; the oxygen is then turned off as the lance is being withdrawn. Following this, the vessel is turned down to decant most of the slag. More slag is then pulled from the vessel by raking, after which a lime dam is formed at the mouth of the vessel to hold back the remaining slag when the steel is poured into a ladle. Blowing time in the vessels is 20 to 22 minutes with an oxygen input of 2500 cubic feet per minute at 130 pounds per square inch of pressure. Oxygen consumption is 2000 cubic feet per net ton of ingots. The time from charge to charge is between 30 to 35 minutes, including time for charging, changing pipes, steel sampling and testing. Figure 14—13

The end point is controlled visually by the drop of the flame at the mouth of the vessel at the end of the carbon blow.

The quality of the steels produced by the top-blown basic process is claimed to be equivalent to basic open-hearth steels of the same chemical composition.

FIG. 14—13. Progress of refining in a top-blown, basic-lined vessel (after Roesner).

shows the progress of refining in a 5-ton experimental top-blown vessel.

Temperature Control—A major problem in the top-blown basic process is one of decreasing rather than increasing the temperature. This probably is associated with the use of oxygen rather than air for blowing. The principal method used for temperature control is regulation of the quantity and timing of scrap additions. Air or steam has not been used to any extent for cooling of the bath.

Deoxidation Reactions—It has been mentioned previously that, for most pneumatic steels produced, ferro-manganese is commonly used for deoxidation. Since Austrian iron blown in the top-blown basic process is very high in manganese content (1.6 to 2.5 per cent), the use of manganese additions to the ladle is frequently unnecessary. Further, it has generally been observed that the iron and iron oxide content of the basic slag from the top-blown vessel is lower than that obtained in other pneumatic processes. In these cases, the major control of deoxidation may be exercised by control of the final bath temperature.

Nitrogen and End-Point Control—No special means of controlling the nitrogen content of top-blown basic steels are necessary since the final steels produced contain from 0.002 to 0.004 per cent of nitrogen.

THE EQUIPMENT ARE ONLY TO SHOW THE FUNDAMENTALS, THE PRINCIPLES.

Chapter 15

THE OPEN-HEARTH PROCESSES

SECTION 1

SOME GENERAL FEATURES OF THE SIEMENS PROCESS

Early History of the Process—The phenomenal success of the Bessemer process, coupled with the ever-increasing demand for steel, attracted many other inventors to the study of new and improved methods of steelmaking. Of all the methods which received attention, the only process which was destined to become a rival of the pneumatic process was developed through the invention of the regenerative principle by Karl Wilhelm Siemens who, although German-born, was a naturalized British citizen.

Siemens' early work with the regenerative principle as applied to steam engines showed that a very great saving of fuel and very high temperatures could be obtained by its use and, at the suggestion of his brother, Frederick, he turned his attention to the application of the principle for producing high temperatures in furnaces. The first experimental furnace was built in 1858, when it was discovered that, especially with large furnaces using solid fuel, many difficulties were to be overcome if the full efficiency which the principle promised was to be realized.

After two years or more of experimentation, Siemens fell upon the plan of gasifying the fuel prior to burning it in the furnace, whereby he found that most of the difficulties could be overcome. Thus, a correlative development of the regenerative furnace was the **gas producer**. Siemens' patent covering the successful furnace design specifically mentioned the possibility of using the furnace for the production of steel. An early design of a Siemens steelmaking furnace, with gas producer, is shown schematically in Figure 15-2.

In the ferrous industry, some of the early uses Siemens made of the furnace were for puddling, reheating iron and steel for forging and rolling, and for melting crucible steel. Siemens next turned his attention to the manufacture of steel in his furnace and, though many trials were made at different works, he met with only indifferent success. Finally, like Bessemer, he found it necessary to erect a steel works of his own. These works were located in Birmingham, England, and were employed at first in a remelting process by which steel of the best quality was obtained from processing such scrap as old rails, plates, and so on.

In the meantime, Siemens was busy developing the idea that steel could be made from pig iron by oxidizing the carbon content of the latter with iron ore and, by the year 1868, proved that this method, which came to be known as the **pig and ore process**, could be employed successfully. He next turned his attention to evolving a method whereby steel could be produced directly from the ore, thus dispensing with the blast furnace. In this feat he actually succeeded, but the cost of production was many times that of producing steel from pig iron. Subsequent events have proved that it is more practical

and economical to employ the blast furnace for the primary reduction of the iron ore to pig iron, and from this to make steel in the furnace which has been evolved from Siemens' original designs.

Principles of Siemens' Pig and Ore Process—Briefly, the method of Siemens was as follows: A rectangular covered hearth was used to contain the charge of pig iron or pig iron and scrap (see Figure 15-2). Most of the heat required to promote the chemical reactions necessary for purification of the charge was provided by passing burning fuel gas over the top of the materials. The fuel gas, with a quantity of air more than sufficient to burn it, was introduced through ports at each end of the furnace, alternately at one end and then the other. The products of combustion passed out of the port temporarily not used for entrance of gas and air, and entered chambers partly filled with brick checkerwork. This checkerwork, commonly called checkers, provided a multitude of passageways for the exit of the gases to the stack. During their passage through the checkers, the gases gave up a large part of their heat to the brickwork. After a short time, the gas and air were shut off at the one end and introduced into the furnace through the preheated checkers, absorbing some of the heat stored in these checkers. The gas and air were thus preheated to a somewhat elevated temperature, and consequently developed a higher temperature in combustion than could be obtained without preheating. In about twenty minutes, the flow of the gas and air was again reversed so that they entered the furnace through the checkers and port used first; and a series of such reversals, occurring every fifteen or twenty minutes, was continued until the heat was finished. The elements in the bath which were oxidized both by the oxygen of the air in the furnace atmosphere and that contained in the iron ore fed to the bath, were carbon, silicon and manganese, all three of which could be reduced to as low a limit as was possible in the Bessemer process.

Thus, as in all other processes for purifying pig iron, the basic principle of the Siemens process was that of oxidation. However, in other respects, it was unlike any other process. True, it resembled the puddling process in both the method and the agencies employed, but the high temperatures attainable in the Siemens furnace made it possible to keep the final product molten and free of entrapped slag. The same primary result was obtained as in the Bessemer process, but by a different method and through different agencies, both of which imparted to steel made by the new process properties somewhat different from Bessemer steel, and gave the process itself certain metallurgical advantages over the older pneumatic process. These advantages will be discussed later in this section.

FIG. 15-2. Schematic arrangement of an early type of Siemens furnace with about a 5-ton capacity. The roof of this design (which was soon abandoned) dipped from the ends toward the center of the furnace to force the flame downward on the bath. Various different arrangements of gas and air ports were used in later furnaces. Note that in this design, the furnace proper was supported on the regenerator arches. Flow of gas, air and waste gases were reversed by reversing the position of the two reversing valves. The inset at the upper left compares the sizes of one of these early furnaces with a modern 200-ton open hearth.

Mechanical Changes and Improvements in the Siemens Process—As would be expected, many variations of the process, both mechanical and metallurgical, have been worked out since its original conception. Along mechanical lines, various improvements in the design, the size, and the arrangement of the parts of the furnace have been made. Originally, the furnaces had a capacity of only four or five tons, but now the size ranges generally from 100 to 150 tons, though in isolated cases as low as 40 tons or as high as 600 tons.

The early development of the Siemens steelmaking process was retarded by the lack of refractory materials capable of withstanding the high temperatures and the chemical reactions of the process. Even in today's advanced stage of development of the process, it is recognized that additional production and improved steel quality may be possible of attainment if new or improved refractories eventually make feasible a sustained operation at higher temperatures.

The Siemens process now is known more generally, at least in this country, as the open-hearth process. The name "open hearth" was derived, probably, from the fact that the steel, while melted on a hearth under a roof, was accessible through the furnace doors for inspection, sampling, and testing.

Metallurgical Improvements—The hearth of Siemens' furnace was of acid brick construction, on top of which the bottom was made up of sand—essentially as in the acid process of today. Later, to permit the charging of limestone and use of a basic slag for removal of phosphorus, the hearth was constructed with a lining of

magnesite brick, covered with a layer of burned dolomite or magnesite, replacing the siliceous bottom of the acid furnace. These furnaces, therefore, were designated as basic furnaces, and the process carried out in them was called the basic process.

The pig and scrap process was originated by the Martin brothers, in France, who, by substituting scrap for the ore in Siemens' pig and ore process, found it possible to dilute the charge with steel scrap to such an extent that less oxidation was necessary. Since the time of the Martins, these processes have undergone various modifications, chief of which are those known as the Talbot, the Campbell, the Bertrand-Thiel, and the Monell processes. These latter processes have become obsolete, and they did little to determine modern practice, except that Talbot and Campbell did exert an influence which still is reflected in tilting-furnace practice, as discussed in Chapter 17.

Advantages of the Siemens Process—The advantages offered by the Siemens process may be summarized briefly as follows: (1) By the use of iron ore as an oxidizing agent and by the external application of heat, the temperature of the bath is made independent of the purifying reactions, and the elimination of impurities can be made to take place gradually, so that both the temperature and composition of the bath are under much better control than in the Bessemer process. (2) For the same reasons, a greater variety of raw materials can be used (particularly scrap, not greatly consumable in the Bessemer converter) and a greater variety of products may be made by the open-

hearth process than by the Bessemer process. (3) A very important advantage is the increased yield of finished steel from a given quantity of pig iron as compared to the Bessemer process, because of lower inherent sources of iron loss in the former, as well as because of recovery of the iron content of the ore used for oxidation in the open hearth. (4) Finally, with the development of the basic open-hearth process, the greatest advantage of the Siemens over the acid Bessemer process was made apparent, since the basic open-hearth process is capable of eliminating phosphorus from the bath. While this element can be removed also in the basic Bessemer (Thomas-Gilchrist) process, it is to be noted that, due to the different temperature conditions, phosphorus is eliminated before the carbon in the basic open-hearth process, whereas the major proportion of the phosphorus is not oxidized in the basic Bessemer process until after the carbon, in the period termed the afterblow. Hence, while the basic Bessemer process requires a pig iron with a phosphorus content of 2.00 per cent or more in order to maintain the temperature high enough for the afterblow, the basic open-hearth process permits the economical use of iron of any phosphorus content up to 1.00 per cent. In the United States, this fact is of importance since it makes available immense iron ore deposits which could not be utilized otherwise because of their phosphorus content, which is too high to permit their use in the acid Bessemer or acid open-hearth processes and too low for use in the basic Bessemer process. For this reason, the basic open-hearth process has become the leading steelmaking method in this country.

The Open-Hearth Process in the United States—As early as 1868, a small open-hearth furnace was built at Trenton, New Jersey, but satisfactory steel at a reasonable cost did not result and the furnace was abandoned. Later, at Boston, Massachusetts, a successful furnace was designed and operated, beginning in 1870. Following this success, similar furnaces were built at Nashua, New Hampshire, and in Pittsburgh, Pennsylvania, the latter by Singer, Nimick and Company, in 1871. The Otis Iron and Steel Company constructed two 7-ton furnaces at their Lakeside plant in 1874. Two 15-ton furnaces were added to this plant in 1878, two more of the same size in 1881, and two more in 1887. All of these furnaces had acid linings, using a sand bottom for the hearths.

A furnace with a basic bottom, rammed from Austrian magnesite, produced basic steel at the Otis plant in January, 1886. Production rate on the basic furnace was so low compared to that normally achieved with an acid bottom that the basic bottom was torn out after four months, and replaced by an acid bottom. Following the Otis installations, the following companies also installed open-hearth furnaces: The Cleveland Rolling Mills (now part of the American Steel and Wire Division of United States Steel Corporation); The Pennsylvania Steel Company (later Bethlehem Steel Company); the Schoenberger Works (now dismantled, but

formerly part of the American Steel and Wire Division); and Carnegie, Phipps and Company (now Homestead District Works of United States Steel Corporation).

It was in the last-named plant that the commercial production of steel by the basic process was achieved first, the initial heat being tapped March 28, 1888. By the close of 1890, there were 16 basic open-hearth furnaces operating. From 1890 to 1900, magnesite for the bottom began to be imported regularly and the manufacture of silica refractories for the roof was begun in American plants. For these last two reasons, the construction of basic furnaces advanced rapidly and, by 1900, furnaces larger than 50 tons were being planned.

While the Bessemer process could produce steel at a possibly lower cost above the cost of materials, it was restricted to ores of a limited phosphorus content and its use of scrap was also limited. The open hearth was not subject to these restrictions, so that the annual production of steel by the open-hearth process increased rapidly, and, in 1908, passed the total tonnage produced yearly by the Bessemer process. Total annual production of Bessemer steel has decreased rather steadily since 1908. The main reasons were the flexibility of the open-hearth process, with respect to its ability to produce steels of many compositions, and its ability to use a large proportion of steel or iron scrap, if necessary.

In 1953, approximately 89.5 per cent of the steel produced in the United States came from the basic open hearth, with about 3.5 per cent from the acid Bessemer, and 6.5 per cent from the electric furnace. The preponderance in favor of the basic process for production of steel for ingots is based on the ability of this process to remove phosphorus (and some sulphur) while the acid process is limited to removal of carbon, silicon, and manganese and must use carefully selected raw materials that contain less than specified amounts of phosphorus and sulphur.

At the beginning of 1954, the steelmaking capacity of the United States was divided between the various processes as follows:

Process	Capacity (Net Tons Per Year)
Basic open hearth.....	108,279,490
Acid open hearth.....	815,240
Total open-hearth capacity.....	109,094,730
Bessemer	4,787,000
Electric furnace*	10,448,680
Grand Total	124,330,410

These figures demonstrate the dominance of the basic open-hearth furnace as the preferred source of large tonnages of quality steel. Table 14—I in the chapter on "The Pneumatic Steelmaking Processes" shows the production of steel ingots by various processes over an extended period.

* Includes 40 tons of steel manufactured by the crucible process.

SECTION 2

BASIC OPEN-HEARTH PLANT LAYOUT

Because of their greater extent and complexity as compared with acid open-hearth steelmaking plants, only the arrangement of large, modern, basic open-hearth plants engaged in the production of steel ingots will be considered here.

Layout of the Main Furnace Building—Open-hearth furnaces are housed in large, steel buildings, designed

and arranged to facilitate the charging of the furnaces, the making of the heats, and handling of the finished molten steel.

The furnaces are installed in a long, straight row, approximately along the centerline of the main furnace building, with the same distance between the ends of adjacent furnaces (Figure 15—3). Space may be left at

FIG. 15-3. General view of the charging side of a group of modern furnaces, showing charging machine in left background.

either end of the line of furnaces for storage or other purposes. It is preferred by most designers that not over 12 furnaces be placed in one row. Between each pair of furnaces is a vertical, composite steel column which performs two functions (Figure 15-4). The tall central section of each column rises to a height sufficient to support the main roof truss above it. On opposite sides of this section are two shorter, heavy steel sections that each support one of the tracks of the two electric overhead traveling crane runways that extend the length of the building. The other track of each of the two runways is supported by columns at the two sides of the building. The distance between these columns may be from 75 to 117 feet, depending upon the length of the furnaces. The longitudinal centerline of the furnaces is parallel to the line of the columns between them, but several feet in front, so that the bridge of the charging-floor crane extends over most of the top of each furnace when positioned over it. This permits

the crane hoist to be operated directly over the furnace when occasion demands.

That part of the floor area in front of the row of furnaces is called the charging floor and, in modern shops, it is elevated about 22 feet above the general yard level of the plant as shown in Figure 15-5. The part of the furnace building above the charging floor is 75 to 85 feet wide. Shops with this arrangement are designated as two-level shops, to distinguish them from plants of older design in which the charging floor was at general yard level.

The remainder of the floor space of the building, located on the tapping side of the furnace, is called the pouring floor or pit side, and is at general yard level.

Charging Side—On the charging side of the furnaces and close to them is laid a broad-gage track on which operate the locomotives (usually Diesel in modern plants) that move the buggies which carry the charging boxes loaded with the scrap and other solid ma-

FIG. 15-4. Arrangement of the columns supporting the roof trusses and crane runways of a modern open-hearth furnace building.

FIG. 15-5. Diagrammatic cross-section of a modern open-hearth plant, showing the relative locations and sizes of the various buildings and the disposition of the chief operating units required for charging and operation of the furnace and disposition of the finished steel.

Fig. 15-6. Typical charging machine in position before an open door of an open-hearth furnace, with a charging box engaged by the peel and ready to be moved into the furnace and dumped

materials to be charged into the furnaces. Parallel to this track on the charging floor is a special track of very wide gage on which operate the charging machines, illustrated in Figure 15-6. These electrically operated machines are equipped to pick up the charging boxes (which have a capacity up to 50 cubic feet) one at a time, from the buggies in position before the doors of a furnace, thrust the boxes through an open door into the furnace and turn them to dump their contents on the hearth; following this, the boxes are withdrawn from the furnace and replaced on the buggies (Figures 15-7 and 15-8). The empty boxes then are hauled away and refilled in preparation for the next charge. Two to four charging machines of 10 to 15 tons capacity may be provided.

Electric overhead traveling cranes operating on the crane runway over the charging floor are known as **charging floor cranes**. They have a main hoist designed with capacity for handling ladles of molten iron from the mixer to be charged by pouring into the open-hearth furnaces, and also have an auxiliary hoist for miscellaneous work on the charging side. The main hoist capacity ranges from 100 to 150 tons and the auxiliary hoist capacity may approach 40 tons.

A mixer serves the dual purpose of (1) having a supply of molten pig iron available whenever needed for charging, and (2) mixing successive "casts" or lots of iron from blast furnaces, so that possible irregularities in the iron are smoothed out or compensated. A hot-metal building or mixer building usually is located at one end of the charging floor. This arrangement permits the transfer of molten pig iron (in ladles) from the metal mixer by electric overhead traveling crane or, better, by an electric ladle car running on a separate track laid on the charging floor. In the latter case, the cranes are employed to dump the ladles in charging the molten iron into a furnace. Hot metal mixers have been built with capacities up to 1500 tons. In plants of recent design, the holding capacity has been divided between two mixers, each of 800 tons capacity.

Hot-metal mixers generally are barrel-shaped, constructed of steel plate and lined with suitable refractories. The steel shell of the mixer is mounted on rocker-shaped castings which rest on rollers so that the mixer can be tilted by an electric-motor drive to pour off the desired amount of metal into a transfer ladle for transport to the open hearth furnaces (see Figure 15-9).

Mixers have been lined with natural siliceous rock (high silica content) or dense fireclay refractories. While these types of linings still predominate, more difficult service conditions have led in recent years to trials of superior refractories such as the super-duty fireclay and high-alumina types.

The stockyard where scrap and other solid materials are loaded and the *lean-to aisle* where loaded charging boxes on cars are stored while awaiting charging will be described later.

Pouring Floor or Pit Side—The pouring floor, or pit side, of the furnace building extends along the tapping side of the furnaces. It is usually about 70 to 80 feet wide and as long as the charging floor, but at general yard level. The **pouring platforms** are situated along the inside of the wall of the building, opposite to the back or tapping side of the furnaces. Two to four such platforms are installed, at a height convenient to the tops of the ingot molds standing on mold cars ready for filling (Figure 15-10).

Facilities for relining and drying ladles are installed on the pouring side, and equipment for preparing stopper rods is accessible to or from this area, as are grinding and mixing facilities for preparing plastic refractory mixes. The pouring side may be longer than the charging floor if pits needed for pouring very large ingots are required.

Jib-type cranes of $5\frac{1}{2}$ to 7 tons capacity are installed on the tapping side of each furnace to handle such items as furnace tapping spouts.

Stock Yard—The stock yard where scrap and other solid materials are received and loaded should be lo-

FIG. 15-7. Sequence of operations of a charging machine.

located as conveniently with respect to the charging floor as possible. Stock yards in most modern plants are located parallel to the charging floor, and on that side of the furnaces beyond the furnace stacks. The stock yards are 70 to 100 feet wide, almost as long as the main or furnace building, and preferably are roofed in. Three or four electric overhead traveling cranes of 10 to 15 tons capacity and equipped with lifting magnets usually are required to handle the raw materials. It is preferable to have two levels under the crane runway. The upper, at charging floor level, may have two or three standard-gage tracks on which charging buggies are loaded; the lower or general yard level may have one standard-gage track where melting stock and furnace materials are received and where some scrap may be stocked (Figure 15-5).

Lean-to—Between the stock yard and the charging floor is the lean-to (Figure 15-5). This may be as much as 60 feet wide, and usually is not equipped with cranes. The main floor of the lean-to is at charging floor level, and carries tracks on which the charging cars or buggies carrying loaded charging boxes from the stock yard are stored until needed at the furnaces. The furnace stacks usually pass upward through the lean-to. In the

spaces between columns at the sides of the main floor of the lean-to, enclosures may be built to house furnace control equipment, laboratories, locker rooms, weighing equipment, bins for various ferroalloys, and so on.

Beneath the main floor of the lean-to and at general yard level (Figure 15-5) are installed the waste-heat boilers and the fans that regulate the flow of combustion air to the furnaces. This area usually is equipped with standard-gage tracks.

Trackage—There should be sufficient trackage, interlinked with cross-overs, from the stock yard to the charging floor to prevent interference in the movement of charging boxes on cars and their placement before the proper furnace at whatever time they are needed. It is preferable to use standard-gage track throughout this portion of the plant. This permits the use of a charging car of greater width that can accommodate larger charging boxes than when using narrow-gage track, and this facilitates the charging of scrap and other solid materials. Another advantage is that direct loading in and out of standard-gage railroad cars in all parts of the plant is feasible when standard-gage tracks are available.

Mold Yard—The mold yard is housed in a building located as conveniently as possible with respect to the pouring platforms. In it are facilities for cleaning and coating molds and replacing them on the mold cars.

FIG. 15-8. Sketch showing one method by which the head of a charging machine peel is temporarily locked onto the end of a charging box to permit the box to be turned upside down for dumping its contents onto the bottom of an open-hearth furnace.

FIG. 15-9. Two identical hot-metal mixers, each of 800 tons capacity, installed in a separate mixer building at one end of the charging floor of an open-hearth furnace building. The mixers rotate counter-clockwise to pour molten pig iron into the transfer ladle shown.

For modern plants, it is 70 to 100 feet wide and somewhat shorter than the main furnace building. The mold cars are handled in sets called drags, and for these the tracks are usually paralleled by a platform from which the molds may be inspected and cleaned and the hot tops adjusted. Mold-storage space must be provided, and all facilities are served by two or three electric overhead traveling cranes of 25 to 60 tons capacity. Where the mold yard parallels the main building, a lean-to from the mold yard to the main building provides a desirable cover over the tracks over which mold

cars are transported or on which they are stored ready for placement at the pouring platforms.

Miscellaneous Facilities—Other buildings making up the complete open-hearth plant are the slag yard where slag is broken to proper size and steel scrap recovered from it, the scrap drop where steel scrap is broken or burned with cutting torches into desired sizes, and a stripper building which, in best practice, may be located adjacent to the building where ingots are heated in soaking pits for rolling. After the ingots have solidified in the molds, having been held at the pouring plat-

FIG. 15-10. By manipulating the lever, the pourer opens and closes the nozzle of the ladle to control the flow of molten steel from the ladle to the molds. The operation shown is called "teeming" or "pouring."

STRIPPING BIG-END-DOWN INGOTS

Pressure is applied to the top of the ingot by the ram to hold it down while the projections on the bottoms of the stripper arms engage the lugs on the mold and exert an upward pull to strip the mold from the ingot. The tong arms do not operate when stripping this type of ingot.

STRIPPING BIG-END-UP INGOTS

Projections of the sides of the stripper arms hold down the ingot mold while the tong arms are closed to bite into the projecting hot top of the ingot and then draw it from the mold. Use of the ram is not necessary when stripping this type of ingot, so it is designed to be removed simply by withdrawal of a key.

FIG. 15-11. Schematic representation of the action of an ingot stripper in removing the molds from (left) big-end-down ingots and (right) big-end-up ingots.

forms for periods determined by metallurgical experience, the drag of molds with their contained ingots are drawn by motive power to the **strippers** which usually are special electric overhead traveling cranes. With big-end-down molds, the stripper lifts the mold from the ingot car while a plunger forces the ingot down against the ingot stool on the mold car (Figure

15-11). Molds after lifting from the ingots are transferred by the stripper to a parallel drag of cars. With big-end-up molds, it is necessary to pull or push the ingot up and out of the mold while the latter is held against the stool and car (Figure 15-11). Modern stripper cranes, rated at 200 to 250 tons capacity, usually are designed to handle either type of molds.

SECTION 3

FURNACE CONSTRUCTION

Description—In order to avoid repetition, the following description of the open-hearth furnace is made to serve for both basic and acid furnaces. They are similar with respect to form and arrangement of their parts, the chief difference being in the kind of materials used in constructing their hearths or bottoms in which the metal is refined. The present development of the use of basic materials has introduced basic brick into certain sections of the basic open-hearth furnace structure which may not be permissible in furnaces operating on the acid open-hearth process, because basic material introduced by erosion or spalling into the acid open-hearth slag would interfere with the close control of the acid process.

Since, in this country at least, from the standpoint of the number of furnaces and annual production of steel, the basic process is the more important, the description which follows is based on the basic furnace, and only such parts of acid furnaces as require different materials for their construction are described. However, it should be emphasized that even basic furnaces at present differ as to details of construction, principally because of the different fuels used. The number of the various furnaces and the range of capacities are given in Table 15-1.

Parts of the Open-Hearth Furnace and Their Arrangement—The open-hearth furnace is both reverberatory and regenerative. It is reverberatory in that the charge is melted on a refractory hearth, which is

shallow in relationship to the length of the hearth, by a flame passing over the charge so that both the charge and the relatively low (above the hearth) roof, built of refractory brick, are heated by the flame, with a part of the heating effect on the charge accomplished by radiation from the heated roof. Radiation from the flame is an effect the intensity of which varies with the kind of fuel used and the method by which it is burned.

Open-hearth furnaces are regenerative in that the hot gases (from the combustion of fuel) pass out of the reverberatory furnace chamber through passages into chambers known as **regenerative chambers** containing fire brick. These brick are so arranged as to give a large surface contact with the hot gases, which give up part of their heat to the brick. The direction of gas flow is reversed periodically, and the cold incoming air for combustion (and the fuel gas, if necessary) is pre-heated in the regenerative chambers so as to increase the temperature of the flame by a very considerable amount above that which could be obtained by burning the same fuel without pre-heating the combustion air (see Figure 15-12).

The parts of the open-hearth furnace and their arrangement are shown in Figures 15-13, 15-14, 15-15 and 15-16. From these illustrations, it will be observed that an open-hearth furnace consists of the furnace proper, containing the covered hearth on which the charge is placed; ports for admitting the fuel and air for combustion to produce a flame which flows over

FIG. 15-12. These diagrams show the function of the checkers in preheating air for combustion in regenerative furnaces. Fuel is admitted to the furnace at the same end as the preheated air for each cycle.

the charge from the incoming port to the outgoing port; **regenerative chambers** containing brick known as the **checker-work**, or **checkers**, which store up heat transferred to them from the products of combustion, and subsequently impart a large part of this stored-up heat to the fuel (when the fuel gas is preheated) and to the air for combustion; **fantail flues** and **uptakes** connecting the regenerative or checker chambers with the furnace

proper; **slag pockets** which are located at the base of the uptakes; **flues** leading from the air supply (and the gas supply, if producer gas is used) to the regenerative chambers, with connections to the **stack** and to the **waste-heat boiler** (when the latter is installed); **valves** or **dampers** (Figure 15-16) for regulating flow of air, fuel gas and waste gases; and the **stack** itself.

The furnace proper is located with respect to the level of the charging floor so that it can be charged easily. It rests on steel bed beams which are supported, in modern practice, on steel columns which are bricked in for protection from the heated atmosphere and from molten slag or metal.

The slag pockets, regenerator chambers, flues and valves are located on a lower level in an area known

FIG. 15-13. Sectioned schematic plan (not to scale) of the arrangement of a liquid-fuel fired open-hearth furnace, showing location and names of principal parts (see also Figures 15-14, 15-15 and 15-16).

FIG. 15-14. Vertical section across the width of an open-hearth furnace, not to scale, corresponding to Section B-B of Figure 15-13, indicating names and relative locations of principal parts.

FIG. 15-15. Diagrammatic vertical section (not to scale) along the length of a liquid-fuel fired open-hearth furnace, corresponding to Section A-A of Figure 15-13, giving nomenclature of major parts.

FIG. 15-16. This diagram illustrates the principal parts of an open-hearth furnace, sectioned to show as much as possible of the interior. The heavy curved arrows indicate the direction of the flow of preheated air, flame, and waste gases when a liquid fuel is fired through a burner in the trench at the right end of the furnace. The five doors shown are in the front wall of the furnace, and the checker chambers extend under the charging floor, which is not shown. When reversal of firing takes place, the function of the uptake is reversed, and it becomes the downtake. (See also Figures 15-13, 15-14, 15-15 and 15-17 for some additional details of construction.)

as the cellar, the general ground level of which is, in modern plants, twenty-two feet below the charging-floor level. The base of the stack is set on an approximate level with the bottom of the regenerator chambers.

The Furnace Proper—This is a rectangular brick structure, supported on the sides and ends by steel buckstays in the form of steel beams, channels, or (for the walls on the front and back of the hearth) slabs, bound together at their tops, both longitudinally and crosswise above the furnace chamber and ports, by steel struts and tie rods. The buckstays rise vertically from their place of attachment to the steel bed under the furnace hearth, except those supporting the back wall. The back wall buckstays rise vertically from the steel bed to approximately the level of the furnace door sill level, then follow the sloping back-wall contour to approximately the top of the back wall, when they again become vertical.

The Basic Hearth—The hearth (Figure 15-17) covers that part of the furnace below the charging door sill

level, including the bottom and the banks. Older furnaces have "solid" bottoms resting on concrete foundations. Such construction would not be duplicated with present standards of construction. Modern furnaces have "pan" bottoms of closely spaced steel beams covered with steel plates and, thus, the spaces between the beams under the bottom are open to the atmosphere. Wide variations are found in bottom composition and thickness, the latter varying from 15 to 44 inches in different furnaces and varying with the hearth capacity. On the steel bottom plate, the usual practice is to place 1 to 3 inches of insulating concrete or insulating brick, although this may be omitted in the area around the tap hole. Fireclay brick next are laid to a depth of 5 to 12 inches. Over the fireclay brick, from $4\frac{1}{2}$ to 18 inches of basic brick, such as burned chrome brick (used to the greatest extent), burned magnesite, or burned or unburned chrome-magnesite brick are laid. Both the fireclay and the basic brick courses may be laid in increasing vertical thicknesses from the flat

FIG. 15-17. Vertical cross-section of a modern open-hearth furnace through the tap-hole, indicating materials of construction of the various parts. Buckstays and other binding elements are not shown.

centerline section to the banks and hearth ends. From the contour established by the hearth brick construction, the completion of the bottom may proceed according to any of the following general methods:

1. Burned-In Grain Magnesite Bottoms. This is the earliest type of open-hearth furnace basic bottom used after magnesite became available in this country, and was the most commonly used until recent years. After raising the temperature of the furnace chamber to 2900° to 3000° F and maintaining this temperature for 16 to 24 hours, dead-burned grain magnesite, intimately mixed with 8 to 20 per cent of ground basic open-hearth slag, is burned in, or sintered, layer by layer, starting with the upper surface of the basic brick courses mentioned above. The layers are about an inch in thickness, and require about 2 to 3 hours of heating to sinter each one at temperatures between 2900° and 3000° F. Thus, the bottom is built up gradually to the desired thickness and contour. The final contour must provide for proper drainage of steel and slag from the furnace through the tap hole.

During the burning-in process, the slag content of the bottom-making material may be decreased as the total burned-in layer increases in thickness. When the hearth contour is of the proper shape and elevation, the bottom is "slagged"; in this step the banks of the hearth are dusted with ground basic open-hearth slag which fuses and runs down to form a pool on the bottom. This pool shortly is drained off through the opening at the tap hole. The hearth then usually is chilled, after which the furnace must be brought back to operating temperature. Any cracks which appear in the burned-in bottom then are filled with fine magnesite, after which the furnace is charged.

2. Rammed Magnesite or Plastic Chromite Sub-Hearths with Burned-In Working Hearth. The rammed or plastic type of bottom is being employed to a considerable extent, the rammed subhearth replacing an equivalent thickness of burned-in magnesite, thus permitting faster installation which makes it possible to charge the furnace sooner than in the case of a completely burned-in hearth.

The special, prepared, grain-sized, cold-setting magnesite or dolomite-magnesite materials, containing 5 to 6 per cent moisture, generally are rammed to a depth of 6 to 10 inches with pneumatic rammers, while the plastic chromite mixtures are installed in thicknesses ranging from 3 to 6 inches. On top of the rammed-in bottom

material, after raising the temperature in the furnace chamber to from 2900° to 3000° F and maintaining this for 16 to 24 hours, the top layer of the final bottom, from 3 to 10 inches in total thickness, is burned in with grain magnesite, layer on layer, as described in the previous section on burned-in grain magnesite bottoms.

3. All-Rammed Bottoms. Many of these bottoms have been installed in recent years, as they require a shorter time for installation than other types, and provide more accurate contours. The specially grain-sized magnesite mixtures mentioned previously are rammed in over the top of the brick courses, using forms and careful tamping procedure. When ramming is completed, the bottoms are dried with flames from gas burners, after which they finally are heated to approximately 3000° F for about 48 hours, after which any cracks that develop are filled with ramming material. The hearth then is "slagged" as described previously, chilled, and again dressed with the fine refractory material, after which it is brought up to operating temperature for charging.

The foregoing procedures describe the installation of a new hearth. Such a new hearth will last for possibly five years or more. Its life thus covers the making of possibly 3,000 to 6,000 heats, and is called a "campaign." After each heat is tapped from a furnace during a campaign, it usually is necessary to make at least minor repairs to the banks and bottom. The techniques employed for making these repairs to maintain the furnace in good operating condition are described in a later section.

Basic Hearth Tap Hole—The tap hole, located midway between the ends of the hearth and at a point in the back bank toward which the hearth slopes, should have a continuous fall (about 1 inch per foot) from the lowest level of the bottom. It is about 6 inches in diameter and is formed by first placing a steel pipe through a circular hole in the hearth brickwork which is lined with basic brick. The opening between the pipe and the basic brick is rammed with magnesite, magnesite and chrome ore, or basic bottom ramming material. Before the furnace is charged, the tap hole is filled with burned dolomite, being faced with this same material on the inside of the furnace. In the rear, or tapping-spout end, a mixture of burned and raw dolomite is tamped into the hole. A plug of clay loam completes the sealing of the rear end. Tap hole and spout locations are shown diagrammatically in Figure 15-17 mentioned previously.

A casting on the ladle-pit side of the furnace, known as the **tapping-hole casting**, provides a seat for the **tapping spout** against the tap hole, so that the flow of molten steel from the tap hole through the tapping spout to the ladle is smooth and free from undue turbulence. The tapping spout is formed from a steel plate formed into a U-shaped trough, which is lined with fireclay brick and may be surfaced with fireclay, magnesite, magnesite and cement, magnesite and chrome ore, occasionally with graphite in the mix. A refractory joint of plastic refractory is made between the spout and furnace.

When the percentage of molten pig iron in the charge is high enough to require a slag run-off or flush-off in the period following the addition of the molten metal, provision is made in the back bank and through the back wall, between the tap hole and the end of the furnace, for a **run-off notch**. This is to provide an opening through the back wall through which the early slag may be run off through a spout and into a slag pot. In the case of several modern installations, the sill plate of the middle furnace door is designed to permit the drainage of slag from the furnace so that it may be removed from both the back and front of the hearth (see Section 4).

The Acid Hearth—The hearth of an acid open-hearth furnace is similar in contour to that of a basic open-hearth furnace, the difference in construction being that acid brick instead of basic brick are used in the hearth structure and only acid material is used above the hearth brickwork.

The average capacity of acid furnaces in the United States is approximately 60 tons, and the largest acid furnaces are of 125 tons capacity. A modern acid open-hearth furnace would have the same steel bottom pan as used in the latest designs for basic furnaces.

One and one-half inches of insulating concrete may be used next to the steel bottom plate. Fireclay brick next are laid to a depth of 5 to 11 inches. Over the fireclay brick are laid silica brick to a thickness of 11 to 12 inches. On top of the silica brick, the upper part of the hearth, which receives the charge, is built up with fritted or sintered silica sand to a minimum thickness of 9 inches at the tap hole, and to an increasing thickness progressing towards the ends of the hearth. The drying and heating of the acid furnace preliminary to making the bottom of silica sand are conducted in the same manner as for the basic furnace. Before the furnace is heated to too high a temperature, the tapping hole must be put in shape.

Acid Hearth Tap Hole—In most furnaces, the opening left in the brickwork for a tapping hole is square in section, except at the top, which is arched. This opening, measuring about sixteen inches across, must be lined with some acid refractory material that will set hard and resist the eroding effect of the liquid metal and slag. To form this lining, a tapered plug of iron or wood, from four to ten inches in diameter at the large end, varying in accordance with the size of the furnace, is inserted centrally into this hole in the brickwork, and the space between the plug and brick is rammed full of ground ganister (silica sand) containing a little plastic clay as a binder. When this mixture has set, the plug is removed, and the round opening is filled with anthracite coal, which is covered immediately on the inside of the furnace with a little sand, so the coal will not be burned out during the heating of the furnace. Outside, the coal is held in place with a plug of fire clay. Some shops prefer to use a graphite plug, such as might be made from a used electric furnace electrode. In this case, the plug is surrounded by silica sand and is left

in place while the bottom is being made. The tap hole is approximately 6 to 8 inches in diameter. Some melters prefer to tamp the hole full of ganister containing 5 to 7 per cent moisture, and then dig out with a sharp, curved spoon some of this filling to form a small cylindrical-shaped hole, which is left open until after the bottom and banks have been fritted in. This hole is then stopped as described above.

Making the Acid Bottom—After the tapping hole has been made ready, the heating of the furnace is carried on as described under the basic process. In the meantime, preparations are made for fritting or glazing the sand bottom and banks. As a first step, enough sandstone or granite chippings, if such chippings are procurable, are scattered over the bottom and banks to cover the surface. Then, as soon as the furnace has come to a red heat, more fuel is admitted and the valves are reversed at about twenty-minute intervals until these chippings begin to fuse. This procedure permits the bricks in the banks and bottom to absorb more heat than if sand is spread directly upon them, and the partly fused chippings form a better bond between the almost infusible silica brick and the sand fritting. By means of shovels, rabbles, and long-handled spoons, silica sand is now spread evenly over the surface of the bottom and banks to a depth of about one-fourth inch, and the heating is continued until this sand begins to fuse, thus forming a glaze over the entire surface. Another layer of sand is then spread and glazed on as before, and these operations are repeated until the bottom and banks have been built up to the desired thickness, which varies, according to the size of the furnace, from nine to twenty inches. The bottom may now be compared to a big oval dish, the semi-vitrified layers of sand forming practically a solid one-piece wall about the sides and bottom.

After the bottom and banks have been fritted properly, or glazed in, the tapping hole is punched through from the outside and again made up as before, using a mixture of anthracite coal or coke and sand, and securing this in place with a plug of fire clay rammed in from the outside, at some shops. The hearth then is filled nearly half full of acid open-hearth slag. If the slag is not at hand, red brickbats or other easily fused siliceous material is substituted, and some light scrap, such as sheet trimmings, is scattered on top. Other shops prefer to add only as much slag as the bottom and banks will absorb. When this charge has melted, rabbles are inserted through the doors and the liquid slag is splashed up against the banks to wash them down. Then the bottom itself is raked over carefully to smooth it, after which the tapping hole is opened and the slag is drained out of the furnace. This treatment tends to consolidate the bottom and banks, and make them much more resistant to the buoyant action of the liquid metal of subsequent charges. According to some practices, the next two or three charges will be small, not over two-thirds the capacity of the furnace, and will consist mainly of cold pig iron. Then, if it is apparent that the bottom is holding well, the size of the charge and the proportion of scrap used may be increased gradually until the furnace is working on its normal charges. Some melters prefer to test each layer of the bottom as it is fritted in by scraping it with sharp rods. When each layer has shown a hard glazed surface, and examination of the material removed in shaping up the tap hole indicates a firm vitrified bottom, the first charge may be of normal size.

The quality of the sand used for this purpose is of very great importance. If the sand is very pure, that is, composed almost entirely of silica, great difficulty is

Table 15—II. Chemical Compositions of Different Sands Used for Acid Open-Hearth Bottoms and Banks

GRADE	Good	Bad	Fair	Fair	Good	Mix*	Mix*

* These sands may be mixed in about equal proportions.

experienced in fritting it on the bottom, while if it contains too high a percentage of impurities, it will be fritted easily but also will be worn away rapidly after the furnace is put into operation. The silica content of the sands, or sand mixtures, that gives the best results is usually between 94 and 97 per cent. No definite figures can be given for the composition of a good sand, because the adaptability of the sand for this purpose depends not only upon the kind and relative amounts of impurities present, but also upon the physical make-up of the sand itself. Certain natural sands, including some beach sands and a few deposits in Ohio and other mid-western states, give the best results. In Western Pennsylvania some of the most desirable material occurs as hard sedimentary rock, which has to be crushed to render it suitable for this purpose. In fineness, this stone is crushed so that all will pass a one-fourth inch screen. Frequently a relatively coarse and pure sand mixed intimately with a certain proportion of a fine and less pure sand will give good service as bottom material, even when either sand alone has proved unsatisfactory. Table 15—II has been found helpful in the selection of suitable sands for this purpose.

Front Wall and Doors—The walls of all open-hearth

furnaces begin on the top course of the brick which form the upper rim of the hearth. The front wall extends from the door sill line to the bottom of the skewback channel that supports the skewback brick on which the roof is supported. The walls, in the larger modern furnaces, are generally at least 13½ to 18 inches thick, being thickest at the base of the wall. Basic brick for basic furnace walls usually are laid up to 12 to 15 inches above the sill line. The courses of brick above these are usually of silica brick where brick arches above the doors are employed and of basic brick when archless door frames are used. With silica walls, it is preferred that the underlying basic brick be chrome-magnesite, their composition being predominantly chrome ore, to limit fluxing of the silica brick. Front walls built entirely of basic brick often employ steel-encased magnesite-chrome brick in which magnesite is the predominating ingredient of the composition. These are "tied" to the furnace buckstays with steel plates laid horizontally between selected courses, usually by spot-welding them to the buckstays, to provide greater stability and resistance to mechanical abuse (See Figure 15—18). Silica brick front walls sometimes are insulated by applying plastic clay-bonded exfoliated vermiculite by a spray gun or trowel to a thickness of 1 to 2 inches.

When the walls are built of basic brick, it is not usual to insulate them, but rather to seal them against air infiltration by using a thin coating of the materials ordinarily used for insulation.

Modern stationary furnaces generally are equipped with five doors. Recently, some enlarged furnaces have had the number of doors increased to seven. Practically all doors in use on open-hearth furnaces are water-cooled, and generally are lined with used or new fire-clay brick, although increasing use is being made of plastic chrome ore, rammed on steel studs set in the steel door plate (Figure 15—19).

A peep hole, called the wicket, is provided on each

FIG. 15—18. Sketch showing how steel plates are inserted between every fourth course of metal-encased basic brick and then welded to bars welded to the solid buckstays to make a more stable front-wall construction for an open-hearth furnace. Note increased thickness of wall near the bottom. (Courtesy, Harbison-Walker Refractories Co.)

FIG. 15—19. A hollow steel casting, through which cooling water is circulated, has a studded recess which is rammed with a plastic refractory to make one type of an open-hearth furnace door.

FIG. 15—20. At the top is shown a section of an open-hearth-furnace main roof, illustrating the ribbed-ring-type of construction. Joints between brick in the rings and ribbed rings are omitted. Note that port roof is of ring-type construction, but not ribbed. Below are three schematic drawings showing differences between the "bonded," "ring" and "ribbed-ring" methods of laying roof brick. These are not sketches of an open-hearth roof, and are intended only to illustrate the three methods of bricklaying.

door to provide for inspection of the interior of the melting chamber, and to provide access to the furnace for dipping out molten samples, for stirring, for poling, and for taking temperature measurements.

The doors slide on water-cooled welded-steel frames which are placed between the front-wall buckstays and against the front wall. The doors are raised and lowered by electric door hoists in modern installations.

The front and back walls of acid open-hearth furnaces are built entirely of silica brick, 13½ inches thick.

Back Wall—The back wall may be vertical, or so-called full sloping (40 to 50 degrees with the vertical), or a compromise between the two. Modern practice dictates a slope which will provide easy maintenance through the doors of the furnace (Figure 15–17). In this case, the back wall slopes in such manner as to be essentially a continuation of the sloping back area of the furnace banks. Underlying the hot face of the sloping back wall are about 13 inches of basic brick, or of basic brick over firebrick. Vertical back walls, like the front walls, may be all basic or silica in the upper sections. Magnesite-chrome steel-encased brick are used quite widely. Back walls, particularly of the vertical type, may be insulated the same as front walls if the brick are silica, restricting the coating to a sealing coat if basic brick are used (see the description of front walls, above).

Main Roof—The main roof of the furnace arches over the hearth from front to back wall between the vertical planes which intersect the junction of the port roofs with the main roof as the port roofs slope down to meet the latter. These planes define where the port ends and the furnace chamber begins. Usually, this line of junction of main roof and port roof is called the **knuckle** (see Figures 15–15 and 15–16).

Silica brick are used almost universally to construct open-hearth furnace roofs, although operating tests have been conducted on basic furnaces whose roofs are built of basic brick set in a sprung arch with the brick suspended and pressure applied to the back skewback by springs. Both **bonded** and **ring** silica brick roofs are used in different thicknesses or combinations of thicknesses, although 12, 13½, 15 and 18 inch roofs are most common.

In the bonded roof, the brick are overlapped to “break” the joints, while in the ring roof, the joints are not broken. Ring roofs may be plain or ribbed. It is common practice to employ the ribbed construction for greater stability. As may be seen in Figure 15–20, the ribs run from front to back of the furnace. The ribs may be 3 to 6 inches thicker than the rest of the roof and extend above the regular roof brick at every third, fourth or sixth ring. The location of the rings depends on the width of the roof span.

In some shops, basic brick are used in the roof adjacent to the front and back skewbacks, generally in alternate rings with silica brick.

The rise of the roof arch is generally 1½ to 2 inches per foot of span. **Skewback brick** (Figure 15–17) which take the thrust of the arch at each of its ends, should be designed very carefully so as to have the angle best suited for distributing bearing pressure, and there should be the minimum number of shapes in one skewback line. In some plants, sloping channels are used to replace the shaped skewback brick.

Roof design and thickness require careful consideration in each plant with respect to maximum economical life as related to the fuels commonly used and normal operating practices. All other parts of the furnace should be designed so as to be “balanced” with roof life and thus require replacement in intervals that are

FIG. 15–21. Schematic diagram (not to scale) showing arrangement of checker system for preheating both air and gaseous fuel for an open hearth. Only half of the furnace and the flues on one side are shown, since the other side of the plan is exactly similar. Upon reversing, the air inlet and gas inlet are both closed and the two valves opened, giving access to the stack, while exactly the reverse operations are performed at the opposite end of the furnace.

even multiples or fractions of roof life. This desirable condition can be promoted through careful selection of refractories and their proper applications.

In producer-gas or natural-gas fired furnaces, of which relatively few installations remain, the ends of the main roof slope to form, with the port roof, a V at the knuckle (Figure 15–21). The roofs of oil-fired furnaces are designed to form a shallower V at this point, a higher level at the knuckle, and a straight contour from knuckle to knuckle (see Figure 15–15). Different types of water-cooled skewback channels are employed

frequently, particularly at the front-wall side of the roof.

Silica roof brick are bonded with silica cement or may be laid dry with a surface grouting of silica cement. In the relatively small number of cases when insulation is applied to furnace roofs, exfoliated vermiculite is employed either as a loose blanket or in plaster form, although an intervening layer of sand or crushed silica brickbats containing a small amount of lime may be used. The total thickness seldom exceeds 3 inches.

Acid open-hearth furnaces have roofs built of silica brick, 12 to 15 inches thick.

Port Ends—The port ends (Figure 15—16) include the port side and end walls, fuel ports, port roof, port slope, and uptakes from slag pockets to the port roof. Some furnaces have wing walls (also called monkey walls) built entirely of chrome-magnesite brick, or faced with these brick and backed up with fireclay brick; they form part of the throats where the gases from the ports enter or leave the hearth chamber and may be water-cooled to maintain their contour, with the consequent effect of maintaining control of the flame.

The end walls may be built completely of silica brick, 13½ to 27 inches thick, or of basic brick from slightly below charging floor level to the port roof, in which case the walls are 9 to 13½ inches thick. The basic brick may be burned or unburned magnesite-chrome and preferably steel-encased, or at least, laid with steel plates which are tied to the port-end buckstays every few courses.

Fuel ports on furnaces fired with fuels other than producer gas consist of water-cooled burners which are usually, but not always, covered by a doghouse of basic brick or silica brick covered with chrome ore, the whole generally supported on a solid, silica-brick arch dividing the uptake on each end of the furnace in the direction of the longitudinal axis of the furnace. Gas may be introduced through the same water-cooled burner as liquid fuel, or may be introduced through shaped brick at the sides of the ports near the uptakes.

Producer-gas fired furnaces require separate uptakes and regenerator chambers for the gas (Figure 15—21). The producer gas ports are of various designs, but the most popular design consists of a water-cooled steel arch-shaped "tank," lined inside and out with silica brick, although the outside surface may be covered with basic brick or chrome ore, particularly at the nose or outlet end. The gas uptakes may be lined with basic brick for some distance below charging floor level and built elsewhere of silica brick. Air uptakes may be built similarly.

The port roof usually is built of silica brick, with a minimum roof thickness of 9 inches except at the knuckle or junction of the port roof slope with the main roof, where the thickness is the same as the main roof (Figure 15—16). The port slopes or floors from edge of uptake to end of hearth are built similarly to sloping back walls with fireclay brick covered with basic brick, followed by a layer of magnesite bottom mixture or chrome ore.

Maintenance of port ends and furnace hearth ends is facilitated greatly by good design in the wind box or chill, indicated in Figure 15—15. This is a triangular-shaped steel box open at both ends, extending at both ends of the furnace across the furnace between the hearth side of the uptake wall and the end of the hearth, which portion of the hearth it supports.

Success has been attained with a port end built entirely of basic brick. Magnesite-chrome steel-encased brick are used, suspended, in both port-end roofs and vertical walls.

Insulation of end walls and port side walls is more common than on other wall surfaces above the charging-floor level and, in general, consists of a sprayed or troweled coat of plastic vermiculite, 1 to 2 inches thick in the case of silica brick and a sealing coat in the case of basic brick.

Modern acid furnaces have port ends (roof, side walls, ends) built of silica brick, the walls 13½ inches to 9 inches thick and the port roof 12 inches thick.

Slag Pockets—The slag pockets extend downward from the bottom of the uptakes (see "Port Ends") to a level which provides sufficient volume for the accumulation of oxides. These oxides are in the form of fine dust carried by the hot exit gases that have passed over the charge. The oxides are mainly iron oxide, but may carry other dust; for example, lime after an addition of burned lime to the furnace. The oxides are deposited from the gases descending from the outgoing port without blocking the entrance of these gases to the fantail flues and regenerator chambers. The walls of the slag pocket are built of silica or fireclay brick or, often, of silica brick backed by fireclay brick walls, usually insulated. False walls of loosely laid used brick generally are used inside the silica brick walls to facilitate slag removal. Slag pocket floors are covered with a layer of sand over hard-burned, low-duty fireclay brick. Location of the slag pockets is shown in Figures 15—14, 15—15 and 15—16.

In a number of cases, the bottoms of the slag pockets are built so as to incorporate some mechanical means of loosening and breaking up the oxide deposit, including means for inserting explosives, so as to shorten the time of cleaning out the pockets at the time of furnace rebuilding.

In the case of acid open-hearth furnaces, the silica brick extends on down from the port ends and uptakes to meet fireclay walls extending from the bottom of the slag pockets half way to the charging-floor level.

The fantail flues (Figures 15—13 and 15—16) are built of silica or of fireclay brick. The slag pockets and fantail walls are insulated with 3 to 4½ inches of diatomaceous or fireclay insulating brick or vermiculite blocks, which may be coated with an inch of plastic vermiculite. This is used, as a rule, on the fantail arches to a depth of 2 to 3 inches. From the fantail, the gases flow to the regenerator chambers.

Regenerator (Checker) Chambers—To obtain sufficient flame temperature and economical fuel consumption, the air for combustion must be preheated and where fuels of low calorific value are used (such as producer gas), the fuel also must be preheated. The preheating is accomplished by a regenerative system which consists of brick chambers partially filled with brick which take up about 60 to 75 per cent of the chamber volume and which are known commonly as checkerwork or checkers. The brick comprising this volume are arranged so as to leave a great number of passages through which the waste gases from the furnace pass on their way to the stack and, later on, as the flow is reversed, the air for combustion and the fuel gas (in the case of producer gas) pass in the reverse direction to be heated on their way to the uptakes and the furnace ports. If producer gas is used, both the air and gas are preheated in separate regenerator chambers, uniting and burning only when they enter the furnace (Figure 15—21). With natural gas, coke-oven gas or liquid fuel, only the air is preheated. The checkerwork and the chamber, flue, uptake, and port walls abstract a large part of the sensible heat from the outgoing waste gases and return it later to the incoming air or to the gas which is being preheated. Since a large number of furnaces now in operation were built originally to use pro-

ducer gas, they were constructed with two regenerator chambers at each end of the furnace, the smaller chamber preheating the gas and the larger the air. Such chambers find use even when employing fuels of higher calorific value, such as natural gas, because all of the chambers are then used to preheat air. Furnaces converted from producer gas to liquid fuel continued to use all chambers for preheat and the air for combustion passed through all of them. With later designs not intended for fuels requiring preheat, modifications have been made to arrange the chambers to obtain the best preheat of the air.

The principal parts of the regenerator system are:

- (1) The chambers enclosing the checkerwork.
- (2) The checkerwork.
- (3) The rider wall system which supports the checkerwork and forms the passages conducting the cooled gases from the checkerwork passages to the exit end of the chamber, or, in reverse, conducting the air from the air-inlet valves and flues to the checkerwork.

The entire system of regenerator chambers, including the roof, checkerwork, side walls and flues, generally is built of high-heat-duty fireclay brick, although silica brick may be used in the top courses of the checkerwork and lower quality clay brick in the flues from chamber to stack. There are a large number of checkerwork designs involving the method of laying the brick, the brick size and shape, and the method of allowing horizontal and vertical openings. Simple brick shapes that can be reused are most in favor (Figure 15-22).

FIG. 15-22. One type of checkerwork construction, showing how simple, rectangular refractory shapes are laid in an interlocking manner to provide a series of smooth, vertical flues.

The brick of the checkerwork usually are laid with fairly large openings, generally 6 inches (or more) square on a horizontal plane, which permits easy cleaning during furnace operation, thus retaining a high regenerative efficiency during a furnace campaign. The regenerator chamber roof is generally a sprung arch although, recently, suspended arches have been used successfully. The latter construction permits a greater checkerwork volume because of greater permissible height of checkerwork and the opportunity to eliminate the division wall for furnaces not using preheated fuels. For maximum efficiency of regeneration and, consequently, of furnace performance, air infiltration through the walls of regenerator chambers, slag pockets and furnace ends must be kept to a minimum. All of these walls should be well sealed. The regenerator chamber walls usually are insulated with $3\frac{1}{2}$ to 4 inches of block insulation of vermiculite, magnesia, or asbestos composition. The outside of the chamber walls, including the block insulation, often are encased with light steel plates. When steel is not employed, the insulating blocks are coated with asbestos or vermiculite cement for seal-

ing. These plastic coatings, or insulating blocks plus coatings, are used to a depth of 3 to 4 inches on the chamber roofs. Vermiculite or diatomaceous concrete may be used on the floors of the chambers. Insulating bricks or blocks of vermiculite or asbestos may be used on the flue walls and arches.

Forced Draft Fans—A forced-draft fan (Figures 15-13 and 15-16) is the most important auxiliary of relatively recent adoption for modern furnaces. When operating on natural draft, the only force causing air flow into the furnace ports from the regenerative system is the heat head or stack effect of the checker chambers and uptakes. Thus, not only the temperature of the air varies from one end of the air cycle to the other, but also the quantity of air. In addition, since the checkers are under a pressure less than atmospheric because of natural draft, air infiltration is induced.

It should be noted that the actual positive and negative pressures within the furnace referred to in discussing forced draft and natural draft are only slight, amounting to only a few hundredths of an inch of water pressure.

The benefits of forced draft are threefold:

(1) The volume of air entering the furnace through the regenerators is maintained constant at a given setting, being influenced only by changes in motor and fan speed or valve settings.

(2) The delivery of air under slight positive pressure to the furnace system by a fan lessens air infiltration through flues, checker chambers, fan tails and slag pockets during the cycle when air is passing through on its way to the inlet port.

(3) Delivery of air under pressure to the furnace constitutes an automatic warning system in the sense that it will cause a decided outflow of heat into the furnace cellar in case of leaks in the auxiliary system. This factor promotes prompt attention by maintenance crews to any leaks that may develop and keeps furnace efficiency at a constant high level.

Flues—The type of flue generally used for modern open-hearth furnaces between the regenerative system and the stack or waste-heat boiler is one which has a relatively flat arched top and is supported by a horizontal concrete pad under the flue with concrete retaining walls on the sides. They generally are built with $13\frac{1}{2}$ inch walls and arches of second-quality fireclay brick. On the top of the arch and between the side walls and the concrete retaining walls is used a layer of insulating concrete or similar material having an insulating and sealing effect. The floor of the flue is paved with second-quality fireclay brick, and between this and the concrete pad underneath is a 6-inch layer of insulating concrete.

Valves—Figure 15-23 shows a modern flue and valve system for an open-hearth furnace. To cover the case of a furnace which uses producer gas for fuel, which must be preheated, the diagram shows the position of the producer-gas inlets to the flue system and the gas-reversing valves, as well as the usual air reversing valves, air-fan connections to the latter, stack valve, and waste-heat boiler valve.

On the left side of the diagram, the source of producer gas is shown cut off from the furnace system since the slide valve "A" is down. Both regenerator chambers or checkers are connected to the stack because slide valves "B" and "C" are raised. The upper port in "C" is closed by the slide valve in the raised position, and air supplied by the forced draft fan is cut off from the air regenerator or checker.

On the right side of the diagram, slide valve "D" is

FIG. 15-23. Flue and valve system for an open-hearth furnace fired with producer gas, having the roofs and parts of the walls of the flues cut away to show valve positions and directions of gas flow. Reversing valves at left are designated in the text as Valves A, B and C, from left to right. Valves at right are Valves D, E and F, from right to left.

open, permitting flow of producer gas to the gas checker. Slide valve "E," lowered, has cut off connection of this checker to the stack, and the upper port in "F" is opened to admit air to the air checker by the same slide that, in being lowered, has cut off this air checker from the stack.

When the fuel is not preheated in the regenerative system (coke-oven gas, natural gas and the liquid fuels), valves "A," "B," "D" and "E" are eliminated, and valves "C" and "F" are the only ones needed. Of these two valves, one can serve each side of the system if the flues from the two regenerative chambers at both ends of the furnace are allowed to merge, or two sets may be employed, one valve for each of the two chamber flues at each end of the furnace to make a total of four valves, operating in pairs, in the case of the larger furnaces.

If the waste-heat boiler is in operation, the waste-heat boiler valve "W" has its slide raised to admit furnace gases to the boiler, and the stack valve "S" is lowered to permit flow of these gases from the boiler to the stack. If the waste-heat boiler is not in operation, the valve "W" is closed and the stack valve "S" is opened.

Figure 15-24 shows a simplified installation of one type of slide valves which could replace the air reversing valves "C" and "F" in Figure 15-23, for a smaller furnace using non-preheated fuel. It also illustrates the upper and lower ports of these two valves.

The sliding dampers or slide valves are fabricated from steel plates and are water cooled. The seats on which they slide are made of cast iron and also are

water cooled. The seats and dampers are machined to provide gas-tight closure.

Waste-Heat Boilers—Up to 33 per cent of the fuel input to an open-hearth furnace (gross heating value of the fuel) can be recovered in the form of steam by the use of a proper waste-heat boiler with an economizer. The 33 per cent figure is based upon the equivalent fuel energy represented by actual steam. Taking boiler efficiency into account (say, 80 per cent) the actual heat recovered equals 33 divided by 80 or 41 per cent equivalent fuel. The waste-heat boiler imposes additional resistance to the flow of waste gases and involves the use of an induced-draft fan (Figure 15-13). This fan, however, actually provides an improvement to the furnace system proper, because of the following reasons: (1) the induced-draft fan assures ample draft to remove waste gases from the furnace system almost regardless of the condition of the checkerwork. (2) Since the induced-draft fan is independent of temperature and temperature variation, and has the power to accelerate the movement of the column of waste gases, it permits more accurate control of furnace pressure.

While conventional water-tube boilers were used formerly in waste-heat recovery, the use of such boilers has been abandoned almost entirely in favor of the horizontal fire-tube type.

Waste-heat boilers, in the modern plants whose general layout was described previously, are located on the ground-level floor of the lean-to building, but, in any case, they must be located close to the stack.

Stacks—While in the case of a modern open-hearth

Fig. 15-24. Arrangement of one type of slide valve controlling flow of combustion air to, and waste gases from, an open-hearth furnace fired with non-preheated fuel. The two sliding dampers are operated simultaneously by the same winch, so that as one slides upward the other slides downward to reverse the directions of flow of air and waste gases through the system.

installation with waste-heat boilers, the induced-draft fans produce the larger part of the total draft effect in exhausting the furnace gases, stacks still must be provided. They must provide enough natural draft to enable the process to be carried on when the waste-heat boilers are on repair, or enough draft when the furnaces are being rebuilt and the regenerative system is being cleaned. This draft during cleaning is needed so that the regenerative system will be kept cool enough to permit entry by the repair crew for cleaning out dust under the checker work. Stacks are brick-lined steel shells, from 150 to 225 feet high above the base, with inside diameters of 7 feet in the case of modern furnaces.

A special type of stack, utilizing forced and induced

draft, forms part of a patented system (the Isley system) which utilizes two forced-draft fans and two relatively short venturi stacks (Figure 15-25). Alternately, one fan with the stack valve open is used to energize an ejector nozzle in the one stack at the waste-gas end while, with the other stack damper closed, the second fan, prevented from blowing air out of the stack because the stack damper is closed, pushes air for combustion to the furnace through the regenerative system at its corresponding end. In order to reverse the flow of air and furnace gases, it is only necessary to close the one stack valve and open the other one, and to regulate the amount of air blown by the fans to supply draft effect and air for combustion.

Fig. 15-25. Schematic arrangement of a special type of stack utilizing the venturi principle for controlling gas flow through an open-hearth furnace. There is a stack for each end of the furnace. Height of these stacks is considerably less than conventional open-hearth stacks that depend largely on natural draft for their operation.

SECTION 4

OPERATION OF A BASIC OPEN-HEARTH

Purifying the Metal—It was stated in preceding Section 3 that, so far as *construction* is concerned, the only important difference between acid and basic furnaces is the fact that basic materials are required in the bottom and banks of the basic furnace, while the acid process requires a bottom and banks lined with silica brick and sand. There is, however, a great difference in their *operation* and in the raw materials used for each, the difference being so great as to make a separate treatment of the two processes from this point necessary. Since the basic open-hearth process is the leading steel-making process in this country, it will be described first. The acid open-hearth process will be described in Sections 9 and 10.

Furnace Attendants and Their Duties—Each furnace requires an operating crew of three men: a first helper, a second helper, and a third helper, and supervising these men is a foreman, called a melter foreman, who has charge of a number of furnaces and their crews. Ordinarily, the first helper has charge of the furnace (with occasional checkups by the foreman) except at the tapping of a heat, and directs any repairs to the furnace hearth between the tapping of a heat and the charging of a succeeding heat or repairs during the heat.

Charging—When a basic open-hearth furnace is ready to receive its charge for the first heat after it is built (or, subsequently, when a furnace bottom or hearth has been replaced by a new one) it is usually considered necessary to use a special charge in which limestone, scrap and cold pig iron are charged in the order given. The amounts of scrap and cold pig iron are proportioned so that when the charge is all melted and the lime resulting from the calcination of the limestone has risen through the melted charge, the carbon content of the bath and its temperature will permit the finishing of the heat to make a product acceptable in the current practice of the steel works. The next three or four heats are made using a molten pig iron charge (if molten iron is available) that is less in amount than the normal molten pig iron charge currently used in the furnaces of the shop, and a correspondingly higher amount of scrap. Following these heats, the normal charge is used. The range in composition permissible in pig iron to be used in the production of basic open-hearth steel is given in Table 12—II.

After the first few charges, proportioning the amount of pig iron and scrap in the charge is usually a matter in which neither the melter foreman nor the open-hearth shop superintendent has a choice. There is a certain amount of scrap produced in the open-hearth process, including (1) that produced in the pouring of the heat into ingot molds, i.e., pit scrap, and (2) rejected ingots and ingots too short to roll, these two items comprising possibly 4 or 5 per cent; in addition there is item (3), the scrap produced when rolling the ingot and secondary products, which is, in general, possibly 25 per cent of the ingot weight. Such scrap usually is consumed in local melting rather than shipped to other company shops or sold. The limiting proportions of the total scrap and pig iron charge, and the proportionate parts of the pig iron in molten and cold forms, are governed and restricted by economic considerations. These economic considerations change with the location of the shop, with respect to the proximity of an adequate supply of raw materials, the amount of molten pig iron available, and the scrap available from integrated units.

In order to consider the matter of the charge for basic open-hearth furnaces in the United States, it is necessary to make a preliminary classification of charges as follows:

Type 1—All Liquid Pig Iron, where the blast-furnace capacity associated with a given shop is in excess of demand. This type of charge is very seldom used because it has been found better, when such a proportion of molten pig iron is available, to oxidize part of the supply of molten pig iron in a Bessemer converter and to charge the incompletely decarburized metal in a special type of open-hearth furnace (see duplex process, Chapter 17), or to speed up the melting rate of the usual open-hearth furnaces by making such blown metal a part of their charge.

Type 2—Liquid Pig Iron and Liquid Steel. This method grew out of the attempt to develop a practical and economical method of using 100 per cent liquid pig iron, as shown in Type 1 (see duplex process). Ordinarily, the charge is molten pig iron and blown metal from a Bessemer converter (where molten pig iron was charged and was blown with air). The greater proportion of the charge to the open-hearth furnace is blown metal in the case of tilting furnaces employed in the duplex process. Blown metal is used at present in stationary open-hearth furnaces for producing only a small proportion of the steel made in such furnaces.

Type 3—Solid Steel (Steel Scrap) and Liquid Pig Iron (with some cold pig iron). A quite common situation calls for the use of solid scrap and molten pig iron. Thus a mill which rolls its own steel ingots and has its own blast furnaces would use this method. Where the supply of scrap is restricted, liquid pig iron may also be used to make up such deficiency of local scrap. The amount of iron ore charged is proportioned to control the carbon content of the bath when it is completely melted.

Type 4—Solid Steel (Steel Scrap) and Solid Pig Iron. Where molten pig iron is not available locally, and where cheapness of available scrap prevents justification for building blast furnaces, the pig iron may be used in solid (cold) form. With the higher proportions of scrap, the use of burned lime as a flux may be advantageous, as mentioned under Type 5.

Type 5—All Solid Steel (Steel Scrap). Where no pig iron is available or the cost makes its use prohibitive, the charge may consist of all steel scrap. The carbon content at which the bath is completely melted is controlled by the weight of coke or other carbonaceous material charged with the scrap. The charging and working of heats of this type require considerable skill and the method is a specialized one not representing common practice.

There are some few cases in which the charge is proportioned between scrap, cold pig iron and molten pig iron in order to secure special features in the quality of the product but, in general, high quality steel may be produced from almost any of the common types of charge.

The solid parts of the charge are placed in the furnace and heated for a sufficient time before charging molten pig iron. The limestone is charged first and scrap is charged directly over the limestone except where ore is charged, in which case the latter is spread over the limestone. Sometimes several charging box loads of scrap are spread on the furnace bottom and the limestone is placed above this. In many shops there is a quantity of cold pig iron which must be used and, in practically all cases, there are pit scrap, ingots too short to roll, scrapped ingots, and broken ingot molds to be consumed.

It is very desirable in most cases to charge the solid materials as fast as the volume of this material permits. Steel scrap may vary from steel turnings and sheet shearings which are graded as "light scrap" to bloom shearings and ingot butts which are in the "heavy scrap" grade. The time required to get the solid charge into the furnace has a marked influence on the time required to make the heat of steel (taken from the beginning of charging to the tapping of the heat from the furnace). Since the scrap comprises the greater part of the solid charge and the weight per unit volume varies over a considerable range, its value as an item of the charge should be based in part on the space it occupies per unit of weight as charged in the furnace. Taking into consideration the space occupied in charging box or furnace and the desire that the total charge will become liquid at a required carbon content, it follows that light scrap requires more pig iron or less ore to be charged than does a heavy grade of scrap. In charging a group of furnaces, it is necessary to consider very carefully the proper proportioning of the amounts of light, heavy and medium scrap. Light scrap requires more charging boxes, which take up much track space and increase the time required for charging. Scrap that is relatively too heavy gives the minimum time in charging, but slower melting.

The charging practice for limestone and scrap is usually the same whether cold pig iron or molten pig iron is used. The quantity of limestone for the greater part of American practice ranges from 5 to 8 per cent of the total metallic charge; burned lime for equivalent fluxing effect being 3 to 4 per cent. The pounds of lime (CaO) required (to be added by these fluxes) must be proportioned on the basis of pounds of silicon, phosphorus and sulphur in the total charge, and silica in the limestone and ore, with additional consideration for the sulphur in the fuel and a knowledge of the quantity of lime and silica provided for slag reactions from the dolomite used as a refractory.

Before considering the amount of ore required to be charged, it is necessary to review the sources from which oxygen is available for the process. These sources are:

- Scale, rust (oxides, carbonates) on solid scrap.
- Oxidizing oxides in slags at different stages. (Oxidizing oxides are reducible oxides FeO, MnO, etc., but not stable oxides CaO, MgO, Al₂O₃, etc.)
- Carbon dioxide (CO₂) resulting from calcination of limestone.
- Oxygen in the liquid metal through direct oxidation of metal when boiling action exposes it to oxidation by the products of combustion.
- Iron ore, roll scale (including heating furnace cinder), sintered ore, nodulized ore, ore briquettes; as charged with initial charge or fed after bath is melted.

The quantity of ore to be charged must be proportioned so that, with the other sources of oxygen avail-

able up to the time the bath is melted completely, the net effect will lead to the desired content of carbon in the completely melted bath with the lime all up from the furnace bottom.

The ore charged is usually spread on the limestone. The quantity varies from 0 to 25 per cent; the high limit being required with unusually large proportions of molten pig iron. The ore charged is usually fine so that it is classified as "soft," but part or all of this natural ore may be replaced with sintered, nodulized or briquetted ore, or imported ore, some of which is harder and contains less fines than domestic ores.

When the per cent of molten pig iron in the total charge is greater than 45 per cent, the resulting higher carbon content makes it necessary to add a considerable quantity of ore after the charge is completely melted, or even to charge ore with the initial charge. With charges of above 45 to 50 per cent of molten pig iron, general practice is to charge ore with the initial charge, and then to feed ore to the completely melted charge if needed.

Solid pig iron is added immediately after the scrap charge or even after the scrap is melted down partially. Molten pig iron, on the other hand, must be added at a carefully judged moment, for the melting and oxidation of the scrap must progress to a stage which insures that the oxides start to work in oxidation of the metalloids of the molten pig iron as soon as it is charged. If the molten metal is added too soon, it will be chilled by the scrap. If the charging is delayed too long and the scrap is too highly oxidized, the carbon content of the bath, when the charge is completely melted, may be too low, and the progress in completing the process delayed. Molten pig iron is poured from the metal mixer or from large mixer type ladles into a transfer ladle. This may be carried on an electric overhead crane all the way to the furnace or it may be placed on an electric transfer buggy and transported to a point near the front of the furnace to be charged, lifted off by an electric overhead crane and its contents poured through a runner or spout inserted through one of the furnace doors by the charging machine (Figure 15-26).

Two of the more common types of charge, which should be listed under Type 3 above, are outlined below.

"Fifty-Fifty" Practice—This term refers to a charge which consists of roughly 50 per cent pig iron and 50 per cent scrap. Such an amount of molten pig iron is large enough to require the use of ore in the initial charge and, depending on the local procedures and efficiency of the furnaces in heat transfer to the charge, a run-off or flush practice is used. Limits of molten pig iron are usually 45 to 55 per cent and the charge may include a relatively small amount of solid pig iron, cast iron scrap or broken ingot molds. With this charge, equipment usually is provided for a run-off or flush practice (see "Melting Down After Molten Pig Iron Addition"). Limestone is normally used since burned lime is more expensive. Fine ore, sintered ore, nodulized ore, or ore briquettes may be used interchangeably. The amount of ore required in the charge is not sufficient to cause serious trouble from violent evolution of combined moisture (water of crystallization), unless an excess of combined moisture is present; i.e., ignition loss is over 5 per cent.

High Molten Pig Iron Practice—This includes those cases in which the percentage of molten pig iron is about 55 to 80 per cent of the total charge and leads to the use of a run-off or flush-off slag for economical operation.

A considerable amount of metallic iron is recovered

FIG. 15—26. Making the hot metal (molten pig iron) addition to an open-hearth furnace. Rate of flow of the hot metal is controlled by the rate at which the crane hook attached to the rear of the ladle near the bottom is raised.

from the ore which is necessarily charged, and this displaces scrap in the charge to the extent that necessary purchase of scrap is lessened. Because of the relatively large amount of ore used, the physical characteristics and chemical composition of the ore are critical in attaining the desired production rate and quality of product. Excessive fineness and higher silica and combined moisture contents are objectionable characteristics. The degree of fineness and combined moisture of many ores may be corrected partially by sintering, nodulizing and briquetting. The charged ore in this practice is placed on the limestone so that the latter is well covered. Since the proportion of scrap is low, it is important to oxidize the scrap well before charging the molten pig iron.

Melting Down the Charge—The melting period really begins when the first scrap has been charged. It is important to melt the scrap and other solid metallic elements of the charge quickly, and to oxidize them by sufficient excess oxygen in the flame so as to have them at such a temperature and degree of oxidation that, on the one hand, the molten pig iron charged will not be chilled by the scrap and, on the other hand, the oxidation of the metalloids of the pig iron will not be delayed by insufficient oxygen supply from the oxidized scrap. Therefore, a high rate of fuel input is desirable with a flame which transfers the maximum number of heat units to the charge over the largest possible area of the charge. This must be subject to the restriction that the roof refractories must not be fused nor the flame extend to the outgoing end of the furnace. When the solid charge is relatively cool in relation to flame temperature, the best condition for heat transfer to the charge exists and the roof will remain relatively cool. Recent

developments in burning fuel over the charge have permitted an increase in rate of fuel input and transfer of heat units to the charge, thus considerably decreasing the time from the start of charging to tapping. These developments include the use of oxygen or compressed air introduced in proper relationship to the fuel stream and the preheated primary air coming in from the "incoming" furnace port. In the case of liquid fuels, the use of more than one burner at each end of the furnace has increased the rate at which heat can be transferred to the solid charge.

Later in the melting down period, after charging molten pig iron, and still later when lime comes up, proportionately more heat units are absorbed by the roof and walls than in the earlier stages of melting when the charge was relatively cold. The fuel input must therefore be controlled carefully.

With proper attention to the techniques of fast charging, e.g., mixing light and heavy scrap, and to maintaining high fuel rate and a flame favoring efficient heat transfer, it is possible, with the aid of an experienced and skilled first helper, to have the temperature and oxidation of the charge advanced to the point which permits charging of the molten pig iron two hours after the start of charging. At this time, part of the solid metallic charge has melted and, mixed with a slag of oxidized metalloids, has trickled down over and through the charge.

Melting Down After Molten Pig Iron Addition—In the period following the addition of hot metal, important reactions take place, dictated by the chemical conditions of the process and the proportioning and timing of the charge. The chemical reactions have to do with removing carbon, manganese, phosphorus, sulphur and silicon

from the metallic bath. First to be removed are silicon and manganese. These are oxidized to SiO_2 and MnO , and become part of the slag. When these have been largely removed from the bath, the oxidation of carbon has already begun and now becomes vigorous. The carbon is oxidized to CO gas which, in escaping, causes agitation of the bath. Eventually phosphorus is oxidized to P_2O_5 and this becomes part of the slag. Sulphur is transferred to the slag and held there as CaS .

When using a high percentage of molten pig iron, the evolving CO gas causes foaming of the slag, which can begin to run from the furnace through openings provided for the purpose. The method of open-hearth operation that involves slag removal in this manner is referred to as **flush practice**. In addition to a notch or hole through the back wall that is common to all furnaces using flush practice, most modern furnaces have in addition facilities for flushing slag from the front of the furnace also. To permit **front flushing**, a notch or trough is cut in the dolomite of the front bank at the center door. Slag running from the flushing hole at the back or pit side of the furnace is carried by a spout to a slag pot set beneath the spout. Slag leaving the furnace over the bank at the front or charging side of the furnace passes through the opening in a hollow casting set in the charging floor and runs into a slag pot set on a car running on tracks at cellar level (see Figure 15-5). This car can be handled readily by locomotives. The openings for slag removal are maintained carefully at the best level to obtain a prompt and adequate slag run-off containing as little metal as possible. The openings in the banks originally are dammed with crushed dolomite, which is raked out to provide an adequate channel for the molten slag. The run-off period may last for an hour in good operating practice. From study of the composition of run-off slags, it is evident that considerable phosphorus and silicon (as oxides) and also sulphur (as sulphides) are removed by the run-off from the furnace. The oxidation of the liquid portion and the melting of the solid portion of the charge continues until the ore in the charge has completed its reaction with the liquid metal.

When carbon monoxide is generated by oxidation of carbon, the turbulence it causes is different in appearance from that caused by release of CO_2 in calcination of the limestone. The CO gas evolution or agitation is more even and gentle, and is commonly called the **ore boil**, and the more violent turbulence caused by CO_2 is called the **lime boil**. It is, of course, true that the oxidation of carbon and resulting gas evolution in the first case results from reaction of carbon with all the reducible oxides in contact with molten metal, not alone the ore, so that it could be more correctly designated as the **iron oxide boil**. This stage of the heat is suppressed in degree of oxidation when scrap is a high percentage of the total charge. Usually it is not until the slag run-off is completed that sufficient heat has been transferred downward through the charge to start the calcination of the limestone and begin the lime boil.

The melting of scrap and solid pig iron charges exhibit the same reactions as those in the practice using molten pig iron. Melting is slower because the total charge is cold at the start, and the vigorous nature of the hot metal reaction is missing. The lime boil occurs later.

One difficulty occurring with high molten pig iron practice when a poor flush is obtained is the tendency toward formation of foamy slags which, containing entrained gas bubbles, are relatively poor heat conductors. This condition results in a cold bath with sluggish action, and a lack of stirring action which further de-

creases heat transfer from the flame. This presents a difficult problem—how to transfer heat from flame to bath while absorption of heat by the bath is limited by foamy slags. Under these conditions, the liquid fuels (and even the gaseous fuels of higher specific gravity) have distinct advantages over a light fuel gas such as coke-oven gas.

As the carbon content of the bath decreases and its temperature rises, the ore boil subsides or changes character, the calcination of limestone becomes more rapid and the lime boil predominates. As it progresses, solid lime rises up through the liquid bath, which is bubbling violently, largely because of the CO_2 given off by calcining limestone; the CO_2 oxidizes some carbon to CO on its upward travel. Lime, by rising to the top of the bath, is now available to replace iron and manganese oxides in the phosphates, sulphates and silicates present and thus become part of the slag, with any excess of lime being taken up to make the slag more basic. The basic property of the slag makes it more capable of retaining both the phosphoric and silicic oxides in the same slag, and renders the phosphate less liable to be reduced with resultant return of phosphorus to the metal. Since the CO_2 released in calcination of the limestone has an oxidizing effect, limestone is equivalent in net effect to a certain amount of ore charged and, theoretically, this oxidizing power is equal to that of 60 per cent by weight of charged ore of the average quality. The lime boil has another function which helps to promote the process. It definitely helps to equalize the temperature and chemical composition of the bath as between levels from top to bottom. The ore boil also has this function but with less effect because in its phase the bath has not advanced as far towards complete fluidity and mobility.

The lime rises to the surface of the bath mostly in lumps that are appreciably smaller than those charged. In the case where burned lime is charged, it finally rises without a preliminary boil. The solid risen lime gradually dissolves in the slag formed from the earlier oxidation of Mn, Si, P and Fe, into which has been introduced some CaO and MgO contributed by erosion of the basic hearth during the early stages of the heat. Special fluxing agents are used in many cases to facilitate the solution of lime lumps in the slag, fluorspar being the one most used.

After the ore boil and the lime boil have subsided, the **working period** or **refining period** begins. The end of the melting period generally is taken as approximately the time when all the lime has risen from the bottom through a substantially melted charge. The usual indication of an approach to the condition known as "lime up" is the cessation of the lime boil.

As removal of carbon from the all-liquid bath proceeds, the melting temperature of the steel rises. This requires an increase in fuel rate to provide an increased transfer of heat to the bath to maintain proper fluidity. Efficiency of combustion of the fuel in this case is aided by a high level of preheat of the air for combustion, and this preheat level can be raised by utilizing the heat in the checkers, by reversing the flow of fuel and air more frequently.

The aims of the working period are: (1) to lower the phosphorus and sulphur contents to levels safely below the maximum level specified, (2) to eliminate carbon as rapidly as possible and still allow time for proper conditioning of slag and attainment of proper process temperature, and (3) to bring the heat to a condition ready for final deoxidation in the furnace or for tapping, with the slag having the proper viscosity and chemical composition and with the desired carbon and oxygen

levels in the bath and the proper final bath temperature for the composition and grade of the steel being produced. The slag must contain large quantities of oxidizing agents during the working period, but must be strongly basic at the end of that period. The conditions under which these aims are advanced to a conclusion depend on the grade of steel being made, whether it is to be finished as of fully killed, semi-killed or rimmed quality, and also on the carbon range specified.

The carbon content of the bath when melted is extremely important. The open-hearth process is used to produce steel with carbon contents as poured which vary from over 1.00 per cent carbon to less than 0.02 per cent. Usually, the procedure is to oxidize the carbon in the bath to a point slightly lower than the final content desired in order to allow for the inevitable increase in carbon content due to the carbon contained in the final ferroalloy additions. Modifications of this method have been used frequently in past practice but in up-to-date practices are used in a relatively small proportion of the heats of steel produced. These modifications involve oxidizing the carbon in the bath to a much lower level than is desired in the finished steel and then "re-carburizing" the metal by addition of molten pig iron into the furnace just before tapping or by adding carbonaceous material, such as coke or coal, to the steel as it runs into the ladle. In all cases, it is necessary to have the heat melt at a higher carbon content than the percentage desired when the heat is ready to tap. The general procedure is to balance the charge in the beginning of the process so that the heat will melt 0.30 to 0.50 per cent carbon above the carbon content at which the heat is to be tapped. This is based on the principle that, during the time required to oxidize this amount of carbon from the bath, ample time for controlling slag and bath composition and temperature will be available.

It was stated above that, in the melting period preceding the working period, a certain proportion of the carbon, manganese, phosphorus and silicon was elimi-

nated from the bath by oxidation. During the working period also the final controlled elimination of these elements is accomplished by oxidation, the sources of oxygen being oxygen from the furnace gases, iron oxides such as feed ore added to the bath, and the blowing of gaseous oxygen by a lance inserted under the metal surface. With respect to the oxidizing influence of the flame, a given open-hearth furnace, burning a selected fuel, has a characteristic range in oxidizing effect which changes to some extent with the life of the furnace. The limit of this oxidizing rate also is affected by the requirement that the maximum heat output must be obtained from the fuel. The oxygen from the iron oxide fed to the bath provides the predominating oxidizing effect so that it, rather than oxidation by the flame, is used to provide the major control element for regulating rate of oxidation. The iron oxide fed also hastens the solution of undissolved lime floating in the slag and generates a boiling action of the bath which assists in removing gases and controlling the temperature.

Lump ore, fine ore, ore briquettes and, to a minor degree, roll scale, are the forms in which iron oxide is added to the bath. Lump ore or briquettes float, so as to project through the slag into the liquid metal and, therefore, give relatively more contact with the metal bath than does fine ore or roll scale. As a result, oxidation occurs much more rapidly when the relatively bulky oxides are used than with the finer, lighter material. Lump ore has been found preferable but at present an adequate supply of "hard" lump ore is becoming more difficult to obtain and the procedure of compacting fine ores into sintered or briquetted masses equivalent to lump ore is receiving increasing attention. The silica content of these iron oxides is important because of the lowering of basicity of the slag by silica. The iron oxide addition causes a decrease in bath temperature, compensated for, to some extent, by the effect of the vigorous action of oxidation in providing a more efficient heat transfer from flame to slag and metal.

FIG. 15—27. A sample of molten steel, withdrawn from the bath by a long-handled spoon, is "killed" with aluminum as it is poured into a small mold.

When the bath receives the oxidizing agents it must be sufficiently hot to prevent freezing by the additions and must also be at a temperature sufficient to promote the endothermic reaction by which oxygen leaves the iron oxide and combines with carbon, silicon and phosphorus (see Section 8).

On the lower carbon grades of steel, it is customary in many plants to add pure oxygen in gaseous form. This is accomplished by inserting a steel lance below the metal surface through one of the furnace doors. The pure oxygen reacts rapidly and raises bath temperature; furthermore, no impurities are added. For each furnace and for each practice in making a desired product there is a rate of adding iron oxide which appears best for the combined objectives of high production rate and adequate quality level. The quantity of iron oxide added and the time between additions is governed by the rate at which heat can be introduced into the bath. If too much ore is added at one time or the additions are too close together, the bath will be chilled and its temperature will approach too closely its melting point. Such a heat would be too cold to tap and pour successfully and, because of its sluggishness, would be very difficult to heat back to proper temperature. After each addition of iron oxide has been allowed time to react, a test is taken (Figure 15—27) in order to make an approximation of the carbon content of the steel by examining the fracture of a broken, cold sample, or to obtain a more accurate carbon determination by chemical analysis, or by an instrument such as the Carbo-meter. In the last half hour or hour of the process, no iron oxide will be added. To obtain the agitation necessary to final oxidation of carbon to the level desired before adding deoxidizers to the furnace or tapping, stirring with steel rods, or the turbulence caused by inserting green-wood poles into the bath, may be employed.

On the steel samples taken soon after the heat is melted, determinations of phosphorus and sulphur are often made by rapid laboratory methods in order to determine what additions and slag-control procedures must follow in order to obtain less than the maximum content specified for these elements. Sulphur removal is relatively slow and difficult to predict and its introduction through the scrap, pig iron, fluxes, fuel and additions should be kept to a minimum. The basicity and viscosity of the slag must be controlled because certain chemical compositions and physical conditions of the slag are favorable for various stages of the heat and finally for various types of heats. Higher basicity levels are necessary to prevent subsequent phosphorus reversion at higher carbon levels. Its chemical composition may be adjusted by additions of burned lime, limestone, iron oxide or silica sand; its basicity is increased through lime additions, and it may be made more fluid by additions of fluorspar and roll scale. CaO is usually provided by burned lime, but sometimes by raw limestone. Fluorspar should be used sparingly. Slag samples may be taken by a spoon either for the purpose of obtaining samples for chemical (or spectrographic) analysis or for the purpose of observing the physical appearance of slag pancakes made by pouring molten slag on a steel plate or in a mold. From experience with slags of many compositions, this latter method of judging the basicity and the iron content of the slag has become dependable. This procedure is discussed further in Section 8 of this chapter.

The appearance of the slag and metal in the furnace, and that of the metal as poured from the sample spoon into a sample mold, are used by furnace operators to check other methods for determination of temperature,

and composition. Each slag or steel sample must be considered as revealing only part of a history of events so that a number of samples are necessary for proper interpretation of conditions and appraisal of future developments.

Actually the first step in slag control is the control of composition of the open-hearth furnace charge since this, with the other factor of the amount of silica and phosphorus removed in the run-off slag, determines the amount of limestone to be charged. Most of the elements oxidized, which combine with lime from limestone or from eroded refractories to form slag, come from the molten or solid pig iron charged. This leads to the conclusion that slag control begins with the control of blast furnace operations. In this connection, it may be pointed out that some sulphur may be eliminated from the molten pig iron on the way from the blast furnace to the open hearth by combining with manganese in the iron, if the sulphur and manganese are above certain limits, and the time of transportation from the blast furnace to the open hearth is long enough, including time in the mixer, to permit the reaction to take place under the proper cooling conditions. Thus, there may be some removal of sulphur before the chemical reactions in the basic open-hearth process take place.

The aims of slag control may be stated as follows:

1. To remove phosphorus and sulphur originally in the bath to below the desired levels in the finished steel.
2. To produce the required degree of oxidation of the bath at the end of the refining period.
3. To arrive at the proper level of oxidation of the bath in the minimum of time consistent with the steel quality desired.
4. To use the minimum quantities of lime and deoxidizers.
5. To produce the required product with the minimum quantity of iron lost in the slag.

The second aim of slag control given above, to produce the required degree of oxidation of the bath at the end of the refining period, will vary within a wide range, depending on the type of steel being produced.

There are three general types of steel, classified according to their behavior in the molds and the resulting ingot structure: rimming steels, semi-killed steels and killed steels. The production of a particular type of steel involves control of the degree of oxidation of the bath at the end of the refining period. How the oxygen content of steel affects the manner in which steel solidifies in the ingot molds is discussed in detail in Chapter 20.

Duration of Various Periods in Production of Basic Open-Hearth Steel—Based upon employing a modern, large, basic open-hearth furnace of 200 to 225 tons capacity, fired with a liquid fuel such as tar or oil, the amount of time consumed during various stages of a heat are as follows:

Melt Down (simultaneous with charging)	2.5 hr.
Hot Metal Addition	0.5 hr.
Ore Boil	3.0 hr.
Lime Boil	1.5 hr.
Working Period	2.5 hr.
Total Heat Time	10.0 hr.

After the carbon level has been lowered by ordinary methods to 0.25 per cent carbon, the use of oxygen thereafter may lessen the working period by 0.5 hr. By improved techniques for burning liquid fuels (oxygen-enriched air for combustion, etc.) the time for melt down gradually is approaching an average of about 2 hours.

SECTION 5

TAPPING AND POURING

Tapping—The finishing temperature of a basic open-hearth steel heat will be in the neighborhood of 3000° F, varying according to the composition and grade of the steel.

When the heat of steel is ready to be tapped, the second helper, working from the tapping side, digs out the clay-loam plug and most of the dolomite with which the tapping hole had been closed before the furnace was charged. The hole either is burned out with oxygen from the tapping side or, according to a recently developed method, opened by a jet tapper which consists of a hollow explosive charge that concentrates its energy when discharged against the obstruction in the taphole, quickly opening the hole. Sometimes, opening of the hole must be completed by driving out dolomite remaining in it by the use of a long steel tapping rod inserted through the wicket hole of the middle door on the opposite or charging side of the furnace (Figure

15—29). When the hole is completely opened, the furnace is emptied of its molten contents, which are directed into the steel ladle through the tapping spout (Figure 15—28). Since the tapping hole is located with its highest level at the lowest part of the hearth and slopes downward to meet the tapping spout, the greater portion of the steel flows out of the furnace before slag appears in the spout and this relatively late appearance of slag permits additions of alloying, recarburizing and deoxidizing materials to the spout and, principally, to the ladle. It is not permissible practice for these materials to come into contact with the slag, since some of the phosphoric oxide in the slag may be reduced and the phosphorus re-enter the steel. Further, a coating of slag on these materials may slow down their melting and solution in the steel and reduce the efficiency of the additions. The vertical axis of the ladle usually is placed with respect to the direction of the tapping

FIG. 15—28. A steel ladle, supported on stands, in position beneath the tapping spout of an open-hearth furnace, near the end of a tap

FIG. 15—29. Workmen, manipulating a long steel rod through the wicket hole of the center door of an open-hearth furnace, drive out the solid material remaining in the partially cleared tap-hole at the rear of the furnace to "tap the heat."

spout so as to give a swirling motion to the metal in the ladle which tends to mix and make it more homogeneous. As soon as the liquid stream from the furnace no longer contains steel, and a depth of slag regulated by good practice remains as a covering for the steel in the ladle (excess slag having flowed from the ladle through slag spouts into a slag pot), the tapping spout is removed by a spout hoist and the ladle lifted from its supporting ladle stands by one of the pouring cranes and conveyed to a position over the ingot molds at the pouring platform.

Ladles—A vertical section through a typical ladle used in basic open-hearth steelmaking is shown in Figure 15—30. The ladle shell itself is fabricated from steel plate by riveting or welding. The horizontal section usually is circular, but a greater capacity often is obtained for a given distance between the trunnions by use of an oval section. The diameter of the ladle increases toward the top to facilitate removal of the shell of metal that occasionally solidifies on the sides and bottom of the interior of the ladle and which commonly is called a *skull*.

The refractory lining of a ladle varies to some extent with the size of the ladle, the thinnest being $3\frac{1}{2}$ inches thick. Thicker linings than this are the rule, and lower portions of the side wall usually are installed with an

extra thickness of brick in that location to compensate for the additional time that this part of the lining is in contact with the molten metal. Extra thickness also may be provided in that portion of the side wall opposite the furnace spout which receives the impact of the stream of metal flowing from the furnace.

The type of brick in most common use is fireclay brick which softens at a temperature as low as 2350°F ; the brick bloats and swells to one and one-quarter times its original size. In service, only a fraction of an inch of the brick beneath the surface exposed to the molten metal actually reaches a temperature above 2300°F , but this is an important consideration since it is this portion which expands (bloats) enough to seal the joints between the individual brick of the lining. This characteristic of ladle brick provides a smooth, tight, almost monolithic working surface that increases ladle life by preventing the penetration of metal into the joints with subsequent premature loss of the lining during removal of a skull. Therefore, though it may have a somewhat lower resistance to erosion by molten steel and slag than a more highly refractory material, the fireclay type of brick usually is the most acceptable for this service. Ladle linings may be installed with a fireclay mortar but, because of the effectiveness of the bloating action in sealing joints, such linings frequently are installed without mortar except as a means for leveling up courses. All ladle linings must be dried carefully by gas, oil, or solid fuel fires prior to use.

The working lining (that next the molten steel) lasts from 10 to 25 heats, and the life varies with the depth, basicity and fluidity of the slag, the composition and temperature of the steel, and the length of time both steel and slag remain in the ladle.

Practically all basic open-hearth steel is cast from the bottom-pour type of ladle shown in the illustration. With this method of pouring, the stopper assembly acts as a valve to control the flow of metal through the nozzle at the bottom of the ladle (Figure 15—31).

FIG. 15—30. (Left) Vertical section of a steel ladle through the trunnions, showing increased thickness of lining in its lower portions. (Right) Side view of same ladle.

Ladle Nozzles—The external size of the nozzle is controlled largely by the capacity of the ladle and the thickness of the lining, but the length must be sufficient to produce a smooth, solid stream of metal through the central orifice, as free from turbulence and spraying as possible. The diameter of the orifice is determined by considerations such as the grade of steel or size of ingot, and may vary from $1\frac{1}{4}$ to 3 inches in diameter. A typical nozzle for a 100-ton capacity ladle would be approximately 6 inches in outside diameter and 12 to 15 inches long, with an orifice $1\frac{1}{4}$ inches in diameter. General purpose nozzles most frequently are made from low heat-duty fireclay and possess properties very similar to those of the ladle brick previously described. They normally are very dense to reduce orifice erosion and, because of their low refractoriness, the surface of the nozzle seat softens to a depth of about $\frac{1}{4}$ inch when in contact with molten steel. This condition provides a soft, yielding seat for the harder stopper head. A new nozzle usually is inserted into the **nozzle retaining plate** after each heat. Above the nozzle seat, a shallow well usually is formed with plastic clay or loam for the purpose of guiding the stopper head into the nozzle seat. A

pocket block or well block made of low or intermediate-duty fireclay burned to brick sometimes is used to form the well. Both nozzle and well must be dried thoroughly prior to use.

Stopper Rod Assembly—A typical stopper-rod assembly, as shown in Figure 15—31, consists of the steel stopper rod, refractory stopper rod sleeves, refractory stopper head, and steel stopper head pin by which the stopper head is keyed to the stopper rod. While other methods for securing the stopper head to the rod are used, the pin and key arrangement is employed by the majority of operators.

The stopper head and nozzle constitute a valve and best results are obtained when one member is harder than the other at steel-pouring temperatures. Since the surface of the nozzle seat is normally quite soft under steel-pouring conditions, the industry now almost universally employs the relatively hard clay-graphite stopper head composed of 15 to 25 per cent graphite blended with various highly refractory clays.

Prior to tapping the heat into the ladle, the stopper is keyed rigidly into the nozzle seat and the entire nozzle and head area are preheated to insure dryness.

The sleeves used to protect the steel stopper rod are manufactured in 9 and 18-inch lengths from fireclay which, when burned, has a similar or somewhat greater refractoriness than ladle brick. Their essential properties are resistance to thermal shock, resistance to slag and metal attack, low thermal conductivity, and snugly fitting male and female parts. A plastic fireclay or air-setting refractory mortar is placed between the joints and the entire series of sleeves is drawn together by the nut on top of the rod. The metal flange at the lower end of the stopper rod takes the thrust of the sleeves during the tightening operation, preventing breakage of the head. After the completed stopper rod has been dried thoroughly and installed in the ladle, the sleeve nut is backed off about $\frac{1}{8}$ inch per foot of stopper rod to provide for the thermal expansion of the sleeves.

As shown in Figure 15—31, the ladle rigging required for raising and lowering the stopper rod consists essentially of a barrel within which a square or cylindrical slide is operated by an appropriate lever arrangement placed at the lower end. The stopper rod is bolted, at its upper end, to a rigid stopper carrier, which in turn is keyed or bolted securely to the upper end of the slide. The entire rigging is attached to the side of the ladle shell in a manner that permits a certain amount of lateral movement of the stopper with respect to the nozzle and the well, through proper adjustment of the adjusting wheel and screw placed within reach of the steel pourer. This adjustment can be made while setting the stopper or during the pouring of the heat.

Proper manipulation of the pouring assembly to start or stop the flow of molten steel to the mold requires a thorough knowledge of the manner in which pouring affects the surface quality of steel ingots as well as an understanding of the refractories and equipment.

Pouring—The pouring operation (Figure 15—10) is critical, first in controlling molten steel so that it does not endanger personnel or damage equipment, second because poor practice in the assembly, adjustment or manipulation of pouring equipment may seriously and adversely affect the surface quality of the product.

One of the most important factors affecting the surface of the ingot and subsequent product is the rate of flow of the pouring stream and the resultant rate of rise of molten steel in the mold. This rate of rise is determined primarily by nozzle size, mold size, temperature and fluidity of the steel and height of metal in the ladle.

FIG. 15-32. Schematic arrangement and nomenclature of parts of a mold assembly for bottom pouring.

The optimum pouring rate is determined primarily by the grade of steel, but is also dependent upon such factors as mold design, type of mold coating, and temperature of steel.

Caution should be exercised to prevent dirt or refractory material from falling into the molds and becoming entrapped in the ingot.

Tun Dish or Basket Pouring—As an alternative to casting steel directly from the ladle to the molds, an intermediate pouring vessel may be used. Such vessels are termed **pouring baskets**, **pouring boxes**, or **tun dishes**. They may be suspended from the main ladle, attached to the pouring platform or carried on an auxiliary carriage, or supported directly by the mold. The method usually involves pouring from the tapping ladle through a large nozzle into the pouring vessel. Steel may be poured into the molds from one or two smaller nozzles in the pouring vessel, one nozzle to a mold.

Use of this practice is more costly than conventional pouring, but offers the following advantages: (1) greater opportunity for non-metallic inclusions to become separated from the metal, (2) less splashing in the mold, (3) the possibility of better control of pouring rates, and (4) a reduction in pouring temperature.

Bottom Pouring—Some of the disadvantages of top pouring may be eliminated through the use of a bottom-pour assembly in which the steel is cast into a funnel lined with refractories, passes down through hollow refractory runner brick, and finally emerges to enter the bottom of various molds through outlet brick (Figure 15-32). The assembly of funnel and vertical runner which receives the molten steel from the ladle is sometimes called a **fountain**. The metal rises steadily in the molds with very little agitation since the main falling force of the stream from the nozzle is absorbed in the runner. One or more molds may be cast from the same fountain, so that the rate of rise can be varied also by

the size and number of molds used. The cost of this operation involves more expense than for top pouring. However, it usually provides better surface quality for certain grades of steel. On the other hand, erosion of fountain and runner brick provides an additional source of non-metallic inclusions which may be a disadvantage in some steels.

Sampling the Steel—During the pouring of the heat, samples of the molten-steel stream from the nozzle (with the flow momentarily slackened) are taken in a steel spoon, containing a required small amount of aluminum wire to "kill" the sample. From the spoon, steel is poured into suitable diminutive cast-iron molds, depending on the method of analysis, to form test specimens for the chemical laboratory where they are analyzed by various methods for the elements which are significant. These are called the **ladle analyses** and are supplemented on some grades by additional **check analyses** on samples taken from blooms, billets or the finished products.

After the pouring of the heat of steel into molds is complete, the slag remaining in the ladle is dumped into slag ladles or pots which are subsequently conveyed to the slag yard on special cars. The mold cars with the filled molds thereon are held at the pouring platform for various intervals of time, depending on the grade of steel made and are then transferred to the stripper cranes where the molds are removed from the ingots or the ingots withdrawn from the molds. The removal of mold from ingot is called "**stripping**" (Figure 15-11).

Ingot Molds are of many types, shapes and sizes. In shape they vary from round, square or oblong molds to those occasional ones that roughly take the form of the section into which the steel is to be rolled. An example of the latter is the mold used to cast an ingot which is roughly of a beam shape which is finally finished as a large, wide-flanged beam. Generally, ingots to be rolled

are of square or oblong cross section, corrugated or fluted in some cases to minimize the cracking of the ingot surface as it solidifies and continues to cool. Ingots to be rolled into blooms or billets are usually of square cross section and those to be rolled into slabs and then into flat-rolled product are usually of oblong cross section. Ingots for forging are generally of a round or many sided cross section, corrugated or fluted.

Ingot cross sections and weights must be established according to the final cross section in rolling and forging, and the weight per piece of final product, with due consideration to the rolling or forging equipment of the individual plants which process the material to the final product.

Molds usually are tapered from one end to the other so that the top of the ingot cast in them is either smaller or larger than the bottom, according to whether the mold is of the big-end-down or big-end-up type (see also Chapter 20). Taper is necessary in both types to facilitate the stripping of the ingot from the mold. In the case of the big-end-up molds, taper also helps to emphasize the freezing from the sides and bottom in such a manner that the last part of the ingot remaining liquid is directly under the hot top, thus promoting soundness. The hot top itself may contain 10 to 15 per cent of the total ingot weight.

Originally hot tops were refractory hollow-tile shapes, or metal casings lined with refractory material,

placed upon the tops of the mold which usually were good for one pouring. At present, the larger proportion of hot tops are refractory-lined steel or iron castings with suitable coatings applied between pourings. The linings may last for twenty-five heats or more. Practically all hot tops, whether of the lined-metal-casing or hollow-tile type, are now inserted into the top of the mold and are supported at various heights depending on the length and required weight of the main body of the ingot. Chapter 20 describes and illustrates the effect of a hot top.

Mold wall thickness ranges from about 4 inches for a 20-inch by 20-inch ingot to about 6 inches for a 32-inch ingot. For molds used to cast large ingots for slabbing mills, the wall thickness may be made somewhat greater for optimum mold life. The life of ingot molds has been found to be a function of the ratio of mold weight to ingot weight.

Ingot Height—There are limits to ingot height, determined by such factors as desirable ingot structure, desirable rimming action in pouring, and design of the pit furnaces in which ingots are heated.

Usually ingot molds are made of blast furnace or cupola iron, a relatively small proportion of cast steel. Big-end-down, big-end-up, open-top and bottle-top, open-bottom, plug bottom, and solid-bottom molds, along with mold coatings, are discussed at some length in Chapter 20.

SECTION 6

KEEPING THE BASIC OPEN-HEARTH FURNACE IN REPAIR

Preparation of the Furnace for the Next Charge—After the runner or tapping spout is lifted and thus detached from the furnace, the slag and any steel that remains in the furnace flow out of the tapping hole into the cinder pit. The second helper must keep the tapping hole open until everything that can flow from the furnace has done so. Fluorspar usually is thrown in on the slag left so that it becomes sufficiently fluid to flow out and its building up on the bottom of the furnace prevented. Often the effective draining of the bottom is prevented by a ridge of lime adhering to the bottom, forming a dam which holds back the slag and steel. Usually at the start, lime ridges hold back only a small portion of the steel. This may seem insignificant, but if allowed to remain, these small pools will develop into larger pools of oxidized steel. Eventually this will result in a bottom boil that will allow the intrusion of steel below the surface by bringing up the basic material forming the bottom of the pools. Liquid slag and liquid steel held back by lime ridges or remaining in the bottom depressions can be disposed of most effectively by blowing with either compressed air or steam. This is done by reducing the fuel input to the furnace and inserting a long steel pipe through the wicket hole of the furnace door and applying air or steam under pressure. After all the steel and slag are removed, the smaller holes may be filled with prepared dolomite; however, the practice of repairing larger ones may differ in that magnesite may be used instead of dolomite, and the work of repairing the bottom may progress by sintering layer on layer of the refractory material in the holes.

To reduce the time required for bottom repairs, prepared mixes high in magnesia content are now frequently used. These require a minimum of time for sintering since the composition is regulated to make them "quick-setting" when properly mixed with specified quantities of water at time of use.

Another method of draining holes is to rabble the metal toward the taphole by means of rabble plates attached to bars. When dry (drained of slag and steel), the bottom is repaired in the same manner as when using air or steam for draining.

The described methods are most advisable from the standpoint of bottom upkeep and economy of time.

There are times, however, when the depth of the hole or its location will necessitate preliminary draining. This may be done with an open tapping hole or by closing it after the furnace has been emptied. Next, fluorspar, scale, or ferrosilicon are placed on the ridges and the high spots of the bottom. The furnace is then operated with a hot flame which tends to soften and disintegrate the high spots in the bottom, allowing the metal in pools to run out of the furnace when the tapping hole is open.

The practice of using erosive material should be resorted to only when absolutely necessary, as it tends to erode the good portion of the bottom as well. Extreme care should be exercised in draining off all eroded material prior to building up the bottom. While the eroded portion of the bottom is being repaired with the fuel on, the entire hearth is examined and simultaneously reconditioned. The fuel is shut off as soon as repairs to the bottom have been completed.

Proceeding to the next step, the second helper and third helper remove the steel that has chilled in the taphole, rake out and free the hole of slag and steel, and close it up with dolomite. A plug of clay is used to seal up the outside of the hole and hold the dolomite in place. The banks are repaired by fettling either manually or with a dolomite machine and the furnace is ready for charging again. Use of the dolomite machine, in which a hopper-fed belt throws dolomite to the required position within the furnace chamber, has become almost standard practice, especially in maintaining the hearths and banks of the larger furnaces. Op-

FIG. 15-33. Schematic diagram of the main working parts and principle of operation of a dolomite-throwing machine. Raising or lowering of the movable pulley (lower right) changes the trajectory of the stream.

eration of one of these machines is illustrated in Figure 15-33.

Generally normal bottom maintenance should be adequate to preserve bottom contour so that all of the steel and slag flows out of the taphole and assures a reasonable amount of time for repairing the bottom. However, during the years of bottom life it is possible that, either due to the method of bottom maintenance or to the prevailing steelmaking practices, the nature and extent of bottom erosion may require general resurfacing. The bottom is then given a thorough cleaning as described above and built up again with 5 to 8 inches of either magnesite or double burned dolomite applied as for a new bottom.

The thick layer of newly sintered bottom effectively reduces bottom delays for approximately 300 to 400 subsequent heats.

Furnace Troubles—In the operation of a furnace, troubles of a very serious nature may occur at any time, unless the furnace is watched closely and carefully handled. Thus, the taphole may break out prematurely if it is not properly tamped and capped, or it may become hopelessly clogged with frozen steel if it is not properly cleaned after each heat. Sometimes, sections of the bottom become detached, and these will rise at once due to the buoyant force of the metal; when this occurs the heat must be tapped at once, and no more heats may be charged until the damaged bottom is repaired. The ports in furnaces fired with producer gas require constant attention to prevent them from building up or melting down, thus changing the angle of the flame and spoiling the optimum heat transfer. Leaks may occur in the walls of the up-takes or down-takes of such producer gas furnaces, so that some gas is burnt before it reaches the hearth. The walls and roof often wear out long before the rest of the furnace needs repairing. Roofs usually last for about 200 heats. The roof can be repaired in a few hours, and a cave-in of the roof is of a serious nature only when it falls when a heat is nearly finished. The most disastrous mishap that can occur to a furnace is a breakout. Breakouts may be caused by several things. A hole near a bank may not have been noticed or may have

been insufficiently repaired, in which case the steel works down into it and gradually makes it deeper until, finally, the metal finds its way through the wall and out of the furnace. Sometimes, owing to a thin spot on the banks or to slag having worked down through the banks from above, the slag gradually cuts its way out through the walls, in which case it is usually followed by steel. Breakouts are always serious matters. Once a breakout occurs, the tapping hole should be opened immediately, and as much of the steel as possible tapped into the ladle or cinder pit. The spread of cinder and metal upon the floor where a breakout has occurred can be contained usually by throwing dolomite around it.

After several hundred heats, the checkerwork has become so badly clogged and the furnace brickwork is so eaten away that it becomes necessary to close down the furnace for general repairs, during which the greater part of the brickwork may be torn out and replaced.

Repair Materials—It is evident that, in making up the bottom and for doing the repair work about a furnace, much depends upon the materials employed. Great care always must be exercised to see that they are of the right chemical composition, and physically suited for the work in hand, as otherwise the best of workmanship in making the repairs will go for naught. The few remarks here are supplemented in the chapter on refractories.

Dolomite is found in deposits similar to those of limestone. Like the latter it varies in composition through quite wide ranges, but generally it may be stated that to be suitable for open-hearth work, it should not have over 1 per cent SiO_2 . Three types of dolomite are used for repairing the furnace:

- (1) Raw dolomite for normal fettling and banking the doors.
- (2) Single burned dolomite prepared locally by burning dolomite in shaft kilns at a temperature of 2200 to 2300°F, for normal fettling and minor bottom repairs.
- (3) Synthetically prepared clinker dolomite in which

lime and magnesia are transformed into a crystalline state by burning at a high temperature in a rotary kiln at which time some iron oxide is introduced as a flux. Generally this material is used to supplement raw dolomite and single burned dolomite, and for bottom repairs of a more serious nature.

Magnesite—Prior to the first World War, practically the entire supply of magnesite was imported from Austria. However, since that time, the demands of the American steel industry have been supplied predominantly by domestic sources, principal of which is Chewallah magnesite in the State of Washington. There are several brands of magnesite available, both of foreign and domestic origin. Magnesites from sea-water magnesia have been introduced in competition with natural magnesite.

Chrome Ore—Chrome ore has always been imported, as the limited deposits so far discovered in the United States and Canada are of an inferior grade for open-hearth use. It is received in the form of small lumps. It

is ground and mixed, in a wet pan, often with some magnesite or suitable bonding material, and is used in repair work where a chemically neutral substance (neither acid nor basic in characteristics) is required, such as in patching flues, tapping holes, ports, and so on.

The composition of an average sample of a satisfactory grade of this ore is shown below.

Ingredient	Per Cent
SiO ₂	4-9
FeO	10-14
MnO	Less than 1
Al ₂ O ₃	10-30
CaO	Less than 2
Cr ₂ O ₃	32-42
Loss on Ignition	1-3

Besides these materials, a quartzite containing 98 to 99 per cent silica is employed at some of the works, while all plants will use large quantities of loam and of fire clay for lining furnace spouts and ladles, for making up stopper-sleeve joints, and for other repair work of minor importance.

SECTION 7

FACTORS AFFECTING ECONOMY OF FURNACE OPERATION

Fuel Consumption—Beside the fuel required for carrying on the metallurgical process of steelmaking from the beginning of charging to tapping the finished heat, it is necessary to burn fuel for heating the furnace to a temperature which permits the operators to begin the "burning-in" of the hearth, and for maintaining the proper temperature during the installation of the furnace hearth. In the periods between tapping of one heat and charging of the next, fuel is required for drying and preheating ladles, drying ladle-stopper rods, maintaining metal mixers at the proper temperature level, heating tapping spouts, drying hot tops, preheating ferroalloys, and sometimes thawing materials. Fuels used for other than actual furnace requirements may be of lower calorific value and consequently cheaper than those needed in the open hearth.

The approach to an economical use of fuel in quantities per ton of steel produced is subject to a number of conditions, such as the kind of fuel used, continuity and rate of production, the design of the furnace (in which hearth area per ton of heat tapped and bath depth are important factors), the proper maintenance of the furnace, its walls, passages, the insulation and sealing against air leakage (on the parts of the furnace system where insulation and sealing are necessary), the degree of control of melting chamber pressure (so as to prevent infiltration of relatively cold air which lowers flame and bath temperature), the proportioning of air supply to fuel burning rate, the control of flame shape, its direction and coverage of the charge and bath, and the promotion of high radiating effects from flame to solid charge and to slag and molten bath, the proportion of molten pig iron used, the elimination of delays in introducing the charge into the furnace, the grade and type of steel to be made, and the care and intelligence with which the furnace is operated. Included in the last item are the very important matters of regulating fuel consumption rate in proportion to metallurgical requirements and of timing the reversals of the regenerator system and the fuel flow so that the transfer of heat from waste gases to preheat the air for combustion is made at the maximum level of efficiency. This timing is determined and carried out in modern practice by the assistance of automatic devices

which are actuated by pyrometers installed in the regenerator system. Modern control and indicating equipment give the furnace operator a good visual indication of fuel rate and help to select a rate of air supply for combustion according to predetermined proportion of air weight to fuel weight.

A list of the controls and instruments related to fuel burning, with which a large number of modern open-hearth furnaces are equipped, follows:

- (1) Control and recording gage for atomizing-steam pressure.
- (2) Control and recording flowmeter for coke-oven or natural gas.
- (3) Control and recording flowmeter for liquid fuel.
- (4) Automatic furnace-pressure control and recording pressure gage.
- (5) Recording draft gage.
- (6) Recording pyrometers for checker temperatures, waste-heat boiler, and stack temperatures.
- (7) Fuel-air ratio indicator.
- (8) Forced-air control, including predetermined automatic fuel-air ratio control.
- (9) Roof-temperature indicator, with automatic roof-temperature control of part of the fuel rate.

The calorific value of fuel usually is expressed by its gross heating value in British thermal units per unit of volume, weight or liquid measure. These concepts were discussed in Chapter 3 on fuels.

Fuel consumption in terms of total calorific value of the fuel used per ton of steel produced usually is expressed in total net heating value of the fuel (millions of Btu) per ton of ingots produced. In the steel industry, the range of fuel consumption by open-hearth furnaces is from 3,000,000 to 4,000,000 Btu per net ton for furnaces in which molten pig iron is used to 4,200,000 to 5,300,000 Btu when the charge is all cold. The heat balance of a modern basic open-hearth furnace is shown schematically in Figure 15-34.

Rate of Steel Production—Practically all of the conditions given above for an economical use of fuel are approximately though not necessarily precisely those which provide maximum rate of steel production for a given quality requirement in the product. Thus it may be

Fig. 15—34. Heat balance of a modern basic open-hearth furnace.

possible to operate a furnace on the low fuel rate of 3,000,000 Btu per net ton of ingots, but it may be necessary to increase this fuel rate by at least ten per cent above this in order to increase the tonnage rate to that desired. The conditions which improve production rate (in addition to those which were discussed in the section dealing with fuel consumption) include the following: relatively large hearth area per ton and relatively small bath depth (these can be considered as matters related to furnace design), size of heat in tons, ability to burn fuel at a high rate in melting down the solid part of the charge, iron ores for the charge which are relatively superior in physical and chemical properties (for example, more massive, low in fines, low in silica and water of crystallization), silicon in the molten and cold pig iron held within a specified maximum, bundling and pressing of light scrap to promote rapid charging, rapid preliminary analyses of bath samples, careful planning and carrying out of the process procedure for each grade and quality of product.

The use of oxygen or compressed air with the fuel stream and of oxygen in eliminating carbon from the bath increase the rate of production. Oxygen or compressed air are of particular value as combustion aids during the melting down of the solid part of the metallic charge (scrap, cold pig iron) and will show the greatest effect in speeding up production rate in furnaces as the ratio of the cold to molten parts of the charge increases, the effect being much less when large proportions of hot metal are used. The oxygen usually is introduced through the regular liquid-fuel burner, with the oxygen jet entering just below the fuel jet.

Twenty-four tons per 1000 square feet of hearth area per operating hour where the area of the bath is taken

on the brick work at the door sill level before rammed or burned-in sections of the furnace hearth are installed (see Section 3) may be considered a satisfactory operating rate for a larger furnace (200 tons and up). The effect of hearth area of open-hearth furnaces on production rate in tons per operating hour for various furnace capacities (rated in size of heat tapped) have been reviewed recently for the American steel industry, and the relationships are given in Table 15—III.

Table 15—III. Effect of Hearth Area on Open-Hearth Production Rate

Hearth Area Per Ton of Capacity	Output in Net Tons per Operating Hour		
	Furnace Capacity		
	200 Tons	150 Tons	100 Tons
3.50 to 4.00	18.4	13.7	9.2
4.00 to 4.50	19.2	14.4	9.6
4.75 and over	20.2	15.2	10.1

When waste heat boilers are used, the exhaust fans in the system assist in maintaining high production rates by maintaining uniform drafts to give the desired removal of waste gaseous products.

The kind of refractories used is important in preventing relatively early failure of the furnace hearth chamber and port ends, in maintaining the contour of the inner surfaces of the areas of the above exposed to high temperature and hot gases and, consequently, an important factor in promoting continuity of operation.

SECTION 8

THE CHEMISTRY OF BASIC OPEN-HEARTH MELTING

In melting down, the item of greatest interest is the action of flame and furnace atmosphere upon the charge. The charge at the beginning consists generally of steel

scrap, but may consist of both cold pig iron and scrap; the pig iron with a low melting range around 2100°F, and the scrap with a melting range of 2500 to 2700°F.

Table 15—IV. Compositions of First Slag Formed in Basic Open-Hearth Heats

Constituent	Slag from Furnace A (Per Cent)	Slag from Furnace B (Per Cent)
SiO ₂	8.54	1.00
FeO*	61.05	78.24
Fe ₂ O ₃ **	11.10	15.31
MnO	2.31	0.81
P ₂ O ₅	0.26	0.14
Al ₂ O ₃	1.98	2.70
CaO	9.13	2.70
MgO	5.48	1.12
S***	0.16	0.25

* As calculated from analysis for ferrous iron.

** As calculated from analysis for ferric iron.

*** Nature of sulphur-bearing slag constituents unknown.

At the start, the temperature is low due to the large heat absorption from the flame by the relatively cold charge. If the fuel contains sulphur, the metal may absorb some of this element as the temperature rises, although the amount may be small if conditions are maintained to give rapid and complete combustion of the fuel with a proper excess of oxygen as noted elsewhere. During the melting, which begins with the metal at the top of the charge and progresses gradually downward, iron may be oxidized by the gases oxygen, carbon dioxide, or water vapor. For a given furnace atmosphere, the amount of iron oxidized will depend on the "bulk density" of the charge, oxidation being the least in pig iron, and the greatest in the lightest steel scrap because of the much greater surface area exposed by the latter to the gases. The degree of oxidation of the scrap is an important factor as the oxides formed are equivalent in action to any ore which might have been charged to furnish oxygen for the elimination process.

The other elements which may be oxidized during melting either by the atmosphere or by oxides of iron from the oxidation of the scrap are carbon, manganese, phosphorus and silicon, all of which are always present, and chromium, vanadium, aluminum, titanium, tungsten, columbium, zinc, etc., all of which may or may not be present. The oxides of some of these elements may be reduced later, in the working period, depending on the amounts present and the composition of the slag formed. In the case of all the oxidizable impurities (except carbon, where the oxidation product is a gas), there will result eventually a condition approaching equilibrium where they distribute themselves between slag and metal as determined by the natural laws governing heterogeneous systems for the chemical reactions involved. Other elements which may be present, such as copper, nickel, molybdenum, cobalt, tin, arsenic, etc., are held in the iron because the iron would have to be completely oxidized before these elements could be removed by oxidation. Proof of these statements may be had by analysis of the first slags formed, which collect with the molten metal in certain parts of the furnace before all the scrap is melted. Results of analyses of two of these slags are shown in Table 15—IV.

CHEMISTRY OF THE ORE BOIL

The reactions following the melting period depend on the make-up of the charge. With a high scrap charge, no ore may be charged, because oxidation of the scrap during melting can furnish the desired amount of oxygen. With no charged ore, or a smaller charge of ore, the limestone charged also may be reduced by the amount

that would have been required to flux the silica in the ore, and the silica from silicon in extra pig iron. Likewise, the oxidizing effect of the CO₂ from calcination of the stone will not be as necessary because of greater oxidation of a larger amount of scrap. The following description is for the usual scrap and pig iron charge, with the pig iron added in the molten condition after a part of the scrap has been melted and the temperature of the hearth and contents is high enough to prevent solidification of the molten metal. As soon as this hot metal is added, reactions begin between the silicon, manganese, phosphorus, and carbon of the pig iron, first with the oxygen supplied by oxidation of the scrap and later with the oxygen supplied by the charged ore as melting progresses. These reactions are exothermic and help to keep the iron molten, as well as contributing to the general supply of heat to the furnace. In general, these elements are oxidized out of the metal in the order silicon, manganese, phosphorus, and carbon. The reactions representing the oxidation of these elements, may be represented by the following equations:

1. Si (in Fe) + 2O (in Fe) = SiO₂ (solid)
2. Mn (in Fe) + O (in Fe) = MnO (solid)
3. 2P (in Fe) + 5O (in Fe) +
4 CaO (solid) = 4 CaO·P₂O₅ (liquid)
4. 2C (in Fe) + 3O (in Fe) =
CO (gas) + CO₂ (gas)

The above reactions express equilibria; that is, they may proceed from left to right or right to left, depending on the relative activities of the substances involved. Reaction (1) results in the formation of the acidic oxide SiO₂, which is insoluble in iron, and in the liberation of heat. Reaction (2) likewise furnishes heat, but results in the formation of the basic oxide MnO, which is only slightly soluble in iron. It will be noted that reaction (3) includes the slag-forming compound CaO. The reason for this is that the high vapor pressure of P₂O₅ precludes the possibility of its existence in the free state, yet analysis of slags always shows phosphorus present as the phosphate, indicating that P₂O₅ is formed in the oxidation. It is probable, therefore, that the oxide of phosphorus combines with lime to form 4CaO·P₂O₅. This is borne out further by the fact that the reaction will be reversed quickly provided sufficient oxygen is not available or the amount of lime over that required to balance the other acidic oxides is insufficient, allowing the phosphorus to return to the metal. Reaction (4) produces the gases CO and CO₂ in proportions depending on the carbon content of the bath. Usually over 90 per cent of the gas is CO, which burns to CO₂, as it bubbles off the bath. The elimination of carbon, therefore, produces no oxide which requires a flux for its removal from the iron. There should be supplied to the furnace atmosphere sufficient air to oxidize the CO to CO₂, in order that oxidizing conditions will obtain.

In order that the transfer of silicon and manganese from the metal to the slag may be visualized clearly, the reactions above must be supplemented by others involving neutralization as well as oxidation. In the case of phosphorus, this neutralization already has been indicated.

Oxidation and Neutralization of Silicon and Manganese—Since silica is strongly acidic and iron oxide and manganese oxide are basic, all or a large part will be neutralized to form fusible silicates of iron and manganese. These will be a major constituent of the first slag, which is formed before the lime boil. As soon as lime begins to rise from the bottom of the furnace, these silicates will be broken down with the formation of calcium silicates as explained later.

Behavior of Sulphur during Melting and the Ore Boil—Compared with the elimination of the other impurities, the removal of sulphur from the steel in the open hearth is relatively inefficient. As a consequence, an attempt is made to keep the amount of sulphur in all the raw materials at a low value. Fuels other than natural gas contain varying amounts of sulphur, and during the melting period it is not uncommon that the scrap may absorb sulphur from the furnace gases. This may be minimized by maintaining more oxidizing conditions in the furnace so that the sulphur is converted quickly to SO_2 , in which form it is absorbed less readily, and by melting rapidly so that the scrap is exposed for the shortest possible time.

It is probable that sulphur in liquid iron exists as iron and manganese sulphides, and it is possible that it exists in the slag either as calcium sulphide or as calcium sulphite or sulphate. Since it is impossible to analyze slag and metal for individual sulphides, no exact chemical mechanism for sulphur removal has been established. It is usual, consequently, to express the reaction as a simple ratio of "sulphur in slag" to "sulphur in metal." Neither iron sulphide nor manganese sulphide can be oxidized in the open hearth, so that the ratio is not affected by the state of oxidation of the metal, but only by slag composition. Higher ratios are found for the more basic slags, containing free lime. As the slag becomes more basic later in the heat, the ratio becomes more favorable for sulphur removal, but in spite of this fact, rarely more than 50 per cent of the sulphur in the metal can be removed without using excessive slag volumes.

CHEMISTRY OF THE LIME BOIL

Before the refining reactions described above are completed, the limestone will have reached its calcining temperature and begun to give off CO_2 in accordance with the following reaction:

This reaction starts at about 1475°F , but progresses only slowly even at higher temperatures, because it is endothermic and because the limestone is charged in large lumps exposing relatively little surface. The CO_2 formed by the calcination reacts with the iron or one of the metalloids to form oxides, and thereby contributes a considerable proportion of the oxygen required by the process. One end product of this oxidation is CO , which bubbles through the bath and produces a desirable agitation which promotes the absorption of heat from the flame by the bath.

The CaO which is a product of the calcination, floats to the slag and replaces iron and manganese oxides as previously stated, forming calcium silicates and aiding in the removal of phosphorus. As more lime becomes available, the basicity of the slag increases, favoring the removal of sulphur by increasing the sulphur-holding power of the slag.

The slag now represents a liquid mixture of some complexity, consisting of calcium silicates, or double silicates of calcium and other bases, sulphates or sulphides, calcium phosphates or double phosphates, iron oxide, manganese oxide, with oxides of the other oxidizable impurities in the charge, plus such compounds as alumina, magnesia, chromic oxide, etc., gathered from ore, limestone, and refractories. The nature of open-hearth slags is very complex and not completely understood, since it is very difficult to study the slag while in the liquid state.

Preliminary Adjustments in the Slag; Objects of the Run-Off—It is evident from the preceding discussion that a certain excess of calcium oxide over that required

to neutralize the silica is necessary to assure lowering the phosphorus content to the small proportion desired in nearly all basic steel. Also, it has been established that for practical phosphorus elimination, the ratio of lime to silica should be at least 2:1, corresponding to the formula $2\text{CaO} \cdot \text{SiO}_2$. Provided the total silicon content in the charge is known and all the slag formed is held in the furnace until the steel is tapped, this relation makes it easy to calculate the total limestone required.

With a high iron charge and, therefore, a high silicon content in the charge, keeping all the slag in the furnace may make it difficult to control the temperature of the bath because of the thickness of the slag layer. The fuel input needed to drive heat through a thick insulating slag layer may also lead to overheating the furnace roof.

Table 15—V. Typical Composition of Hot Metal, Run-Off Slag, and Finishing Slag for 55% and 70% Hot Metal Practice

Heat No.	55% Hot Metal Practice			
	Composition of Hot Metal (%)	Composition of Slag (%)		
		Run-Off	Finish	
1	C —4.26	SiO_2 26.4	18.4	
	Mn—2.36	CaO 14.1	45.0	
	P —0.271	FeO 22.3	12.2

		Al_2O_3 2.5	3.7	
		MgO 5.2	7.3	
		P_2O_5 2.7	2.9	
		S 0.07	0.06	

Furthermore, the silicon content of the charge may not be known at the time the limestone is charged. These difficulties may be overcome by the run-off. If the furnace has been charged to hold the limestone on the bottom and the run-off is timed to begin shortly after addition of molten pig iron and before the lime boil begins, a large portion of the silica and phosphorus are carried out of the furnace, as shown in Table 15—V. The run-off slag, of course, carries with it the iron and manganese oxides in this early slag which may make necessary further additions of ore to obtain rapid elimination of carbon. If the charging of the furnace, the timing of the addition of hot metal, and the run-off are managed skillfully, the silicon remaining to be neutralized with lime can be reduced to a small and almost constant amount, making possible a relatively small limestone charge. Since lime can be of service only in the slag and the calcination of the limestone absorbs heat, holding the limestone charge to a minimum not only decreases slag volume and cost of flux, but gives increased production with a decrease in fuel consumption.

Finally, attention should be given to the timing of the run-off to see that the temperature and fluidity of the run-off slag are sufficiently high and that the state of agitation of the bath is such that mixing of run-off slag and metal is not occurring extensively during the outward flow of slag. If conditions are not thus maintained, a disproportionate loss of metallic iron from the bath will result from metallic particles carried out with the run-off slag.

CHEMISTRY OF THE WORKING PERIOD

The chief aims during this period are to oxidize the remaining phosphorus out of the metal and neutralize it in the slag, to eliminate the carbon to the percentage desired for the start of the finishing period, and to raise the temperature of the bath to a point suitable for finishing and tapping the steel. To eliminate carbon, oxygen dissolved in the bath is necessary, and to oxidize and neutralize phosphorus both oxygen in the metal and calcium oxide in the slag are required, as indicated by the reactions in the discussion above. The rate of oxidation of the carbon must be kept in step with the rise in temperature, since the melting point of the metal bath rises as the carbon decreases. Although it has been pointed out that the reaction between carbon and oxygen dissolved in the bath is exothermic, it is not sufficiently so to furnish enough heat to supply that required for the decomposition and solution of the ore, so that the net over-all reaction requires the addition of heat. In addition, the oxidizing power and basicity of the slag must be controlled to give the best finishing conditions for the different grades of steel. Since it is through the slag that the refining reactions in the metal are accomplished, this control involves control of the temperature and the physical and chemical properties of the slag. The agents for controlling slag composition and properties are numerous, including ores, lime, limestone, sand, fluorspar, etc., but for economy the skilled melter will depend on iron ore, or other iron oxides, and calcium oxide. Any control system must be based upon chemical composition of the raw materials, and upon tests systematically made during the heat. The system may be based chiefly on slag tests, chiefly on metal tests, or both. Whatever the system, it must meet the requirement that it will give the melter a true picture as to the exact changes the metal is undergoing, both in temperature and composition. Much study has been given to all phases of this subject by many investigators and research workers, but practices still vary to

such an extent that no one example can be selected as truly illustrative of the many practices in this part of the process.

Limitations of the Various Systems of Control—All three items for control; namely, temperature, slag composition, and metal composition, as well as the three systems of control, are limited by the ability of the chemist, physicist, and metallurgist to provide reasonably accurate methods for the determination of the temperature and the various components of the slag and metal that are sufficiently rapid to be of value as instruments of control. The following determinations have been developed to a stage that can be considered satisfactory for this work:

1. **Temperature**—While most melters adhere to the empirical methods of "cutting a rod," visual observation, or pouring metal from a spoon to estimate temperatures, these methods gradually are being supplemented. By radiation pyrometers sighted on the roof of the furnace, the heat input to the bath can be controlled at the maximum allowable by the roof refractories. Similar pyrometers installed so as to sight on the checkers are used for automatic reversal of the burners, and the valves in the flues, thereby giving most efficient operation of the regenerative system. The temperature of the metal bath may be measured by "quick immersion" thermocouples or by photronic or radiation pyrometers sighting on the bottom of a tube inserted into the bath. The readings of these instruments are sufficiently reproducible to provide control. Optical pyrometers are used to measure temperatures on tapping and pouring.

2. **Slag Control**—Rapid chemical methods exist for determining contents of total iron, ferrous iron, ferric iron and manganese. The results usually are expressed as the oxides FeO , Fe_2O_3 , and MnO . Chemical methods for determining lime, silica, phosphorus, etc., are too slow for control purposes. Spectrographic methods now exist which will determine the lime-silica ratio in about 5 minutes. Other control tests are primarily physical. Slag pancakes may be used to estimate both basicity and iron oxide content, and serve well when used by experienced melters. Another control method is measurement of fluidity or viscosity by a flow test. The flowing properties of a slag depend on temperature as well as composition.

3. **Metal Control**—The carbon content of the bath can be determined in 3 to 15 minutes, depending on the composition of the bath. Physical tests for carbon, such as fracture, Carbometer, or Carbanalyzer tests, require 3 to 10 minutes. Chemical tests for carbon require 7 to 15 minutes. Manganese can be determined chemically in 10 to 15 minutes, and spectrographically in less time. Reproducible results for oxygen, sulphur, and phosphorus can be obtained in 20 to 30 minutes, where proper facilities for rapid preparation of the sample are available at the open-hearth floor. Chemical analysis for silicon requires 30 to 40 minutes for accurate results, although this element may be determined spectrographically in 5 minutes with accuracy comparable to chemical methods for control purposes. Chemical or spectrographic analysis is frequently made for the "residual elements," such as copper, nickel, molybdenum, chromium, tin, etc., which enter with the scrap.

The spectrographic methods are considerably more rapid than chemical methods for determining residual elements.

Laws of Chemical Action—The general laws of chemical action which relate to reactions within and between slag and metal are given below. As to their practical application to the control of reactions in the open hearth, much depends on the ability of the individual

who is attempting to apply them to analyze the complex mixtures he has to deal with and then isolate each simple component for study in relation to all conditions affecting a given reaction. However, these laws will serve as guide posts in predicting in advance what will happen when changes are made in the conditions existing in the furnace. These laws, five in number, are named and stated as follows:

1. *Nernst's Law of Distribution*—The ratio in which a dissolved substance distributes itself between two immiscible solvents is a constant at constant temperature.

2. *Raoult's Law*—The addition of a non-volatile solute to a solvent causes at any temperature a fractional lowering of the vapor pressure of the solvent equal to the mol fraction of the solute.

3. *Henry's Law*—The partial pressure of a substance in dilute solution is proportional to the mol fraction of the dissolved substance.

4. *Law of Mass Action*—Whatever the initial concentrations of gaseous or dissolved substances involved in any definite chemical reaction, such as may be expressed by the general equation $aA + bB = cC + dD$, the reaction will always take place so that when equilibrium is reached (at a specific temperature) the conditions are such that they will satisfy the equation

$$\frac{(C)^c \times (D)^d}{(A)^a \times (B)^b} = \text{a constant}$$

where (A), (B), (C), (D) denote the molar concentrations of A, B, C, and D in the equilibrium mixtures and a, b, c, and d represent the number of mols of the species A, B, C, D as expressed by the chemical equation.

5. *van't Hoff's Law*—The effect of temperature on a system in equilibrium will be such that the reaction will occur in such a direction as to oppose the change in temperature. For instance, if the temperature is raised, the reaction will proceed in the direction which will absorb heat.

The question of whether or not the open-hearth

process is an "equilibrium" process has been debated often. According to a strict definition of equilibrium, concerned with all phases of the process, obviously the system is not in a state of equilibrium because the conditions are being changed constantly by such things as additions to slag and metal or variation of temperature. At the temperature involved in steelmaking, it is probable that reactions progress at an extremely rapid rate and consequently follow the changed conditions closely. Therefore, it may be said that with respect to the reacting species, or individual reactions, equilibrium is approached closely; while the whole aim of the operator of the furnace is to shift these equilibria, by the means under his control, towards the conditions desired when the heat is to be tapped. There can be no doubt that the natural laws apply to the steelmaking reactions, so that while the thermodynamic relationships between substances reacting in an open-hearth furnace have not been thoroughly determined, the natural laws can at least be used to make intelligent predictions as to the effect of a condition change.

Composition of Slags—A normal basic open-hearth slag, such as the melter has to deal with at the end of the lime boil, may be considered as a fused mixture of the oxides formed by the oxidation of the manganese and metalloids in the charge, together with the calcium oxide formed by the calcination of the limestone, and iron oxides from the charged ore and from the oxidation of scrap. Other oxides which may be present are magnesia and alumina, derived from the ore charged and from the hearth refractories, and oxides of other oxidizable elements which may have been present in the charge in small amounts; for instance, chromium, vanadium, and titanium. Sulphur is also present in the slag, in a form at present unknown. These many compounds are capable of forming numerous chemical and physical combinations so that the properties of individual components may be no indication of the properties of the mixture as a whole.

FIG. 15-35. Phase diagram of the system CaO-FeO-SiO_2 . (From "Basic Open Hearth Steelmaking," published by AIME).

FIG. 15-36. Phase diagram of the system FeO-MnO-SiO₂. (Same source as Fig. 15-35).

A large amount of experimental work has been performed, chiefly by thermal analysis and by the petrographic microscope, to determine the molecular species which may be present in a slag at different stages of a heat. Since both of these methods are subject to limitations, the definite existence of specific species in liquid slag has not been proved, but there is sufficient evidence to lead to the belief that the complex compounds most likely to exist, perhaps partly ionized, at various stages of a heat, include:

2FeO · SiO ₂	} or 2(FeO,MnO) · SiO ₂ ..	{ Iron-manganese silicate
2MnO · SiO ₂		
2CaO · SiO ₂ , or 4CaO · 2SiO ₂ ..		Di-calcium silicate
3CaO · SiO ₂ ..		Tri-calcium silicate
4CaO · P ₂ O ₅ ..		Calcium phosphate
FeO · P ₂ O ₅ ..		Ferrous phosphate
FeS } or (Fe,Mn)S ..		Iron-manganese sulphide
MnS }		
FeO ..		Ferrous oxide
Fe ₂ O ₃ ..		Ferric oxide
CaO (free) ..		Calcium oxide

CaO · Fe₂O₃ Mono-calcium ferrite
2CaO · Fe₂O₃ Di-calcium ferrite

Phase diagrams for numerous slag systems have been developed which are useful in interpreting slag behavior. Examples of two- and three-component diagrams are given in Figures 15-35 to 15-38, inclusive, as well as in Chapter 8 on "Refractories."

Slag Composition in Relation to Refining Reactions—Since the basic open-hearth process is both chemically "basic" and oxidizing in nature, the melter must concern himself with the effects of changes in slag composition on these two factors.

Basicity of a slag may be defined as the ratio of the "basic" components of the slag to the "acid" ones. The most important "base" is CaO, while the most important "acid" is SiO₂; therefore, the simplest basicity ratio is CaO/SiO₂. Numerous refinements of this ratio have been suggested in an effort to arrive at a more exact measure of basicity, but for usual control purposes the simple lime-silica ratio is satisfactory.

Under a pure iron oxide slag the solubility of oxygen

FIG. 15-37. Phase diagram of the system CaO-Fe₂O₃. (Same source as Fig. 15-35.)

FIG. 15-38. Phase diagram of the system $2\text{CaO} \cdot \text{SiO}_2$ - $2\text{FeO} \cdot \text{SiO}_2$. (Same source as Fig. 15-35.)

in pure iron has been found to be a simple function of temperature, varying from about 0.18 per cent at the melting point of iron to 0.34 per cent at 3092°F (1700°C). In the open-hearth furnace neither pure iron nor a pure iron-oxide slag exists, and the solubility of iron oxide has been found on the average to be related to the simple CaO/SiO_2 ratio as shown in Figure 15-39. This average behavior was obtained from a statistical study of a large number of low-carbon heats and serves to point out the effect of slag composition on the all-important transfer of oxygen from slag to metal. For example, if the lime-silica ratio is 2 to 1, then (from the chart) the ratio of "FeO in slag" to "oxygen in steel" is 200 to 1. Then, if the percentage of FeO in the

slag is 10, the percentage of oxygen in the steel is 0.05. This simple relation does not apply to the slags formed during meltdown, but only to the mature slags formed after most of the lime has entered the slag.

The elimination of phosphorus requires that the slag be both highly oxidized and basic. In the early stages of the heat before the lime boil, a variable portion of the phosphorus may be held in the slag and eliminated in the run-off.

Winkler and Chipman, using synthetic slags, showed that increasing the lime-silica ratio produced dephosphorization up to a value of about 2.75. After this value was reached, only an increase in iron oxide in the slag produced further phosphorus removal. The importance of iron oxide in the slag is observed in the furnace where phosphorus may revert to the steel if the iron oxide content of the slag is reduced to too low a value by virtue of a furnace block or the addition of a deoxidizer.

The distribution of sulphur between slag and metal likewise is affected by slag composition. In general, the removal of sulphur from the metal is favored by a large slag volume, a high basicity, and low iron oxide content. However, the latter two items are usually incompatible in basic open-hearth slags, as high basicity (low silica) is usually associated with high iron oxide (see Figure 15-39).

CHEMISTRY OF THE FINISHING PERIOD

The finishing period of a heat is that period in which final adjustments for temperature are made in the furnace and adjustments of composition are made in furnace, ladle, or molds. Since many grades of steels, ranging from nearly pure iron to complex alloy steels, are made by the basic open-hearth process, it is obvious that the practices used during the finishing period will vary widely. At the beginning of this period, the elimination of manganese and the metalloids, with the exception of carbon, should be essentially completed, and the sulphur and phosphorus should be stabilized in a slag of the proper composition to prevent their reversion to the metal. The last of the ore additions will have been made and the carbon content will be falling at a slow, controllable rate to the desired value. The temperature

FIG. 15-39. Oxygen distribution between basic open-hearth steel and slag in the furnace as a function of the simple lime-silica ratio of the slag. (After Fettes and Chipman.)

is controlled by the rate at which fuel is burned, and additions to adjust the composition of the steel are made on the basis of chemical analyses made during this period.

Relation of Carbon to Oxygen in the Metal—The carbon and oxygen contents in the metal are closely related and the elimination of carbon is accelerated by a high proportion of active iron oxide in the slag. The mechanism by which carbon is removed is by diffusion of oxygen from the slag to the steel, where it reacts with the carbon to form predominantly CO and CO₂. The rate of diffusion of oxygen is relatively slow compared to reaction rates at the temperature involved, so that it is probable that the carbon-oxygen reaction closely approaches a state of dynamic equilibrium; that is to say, an equilibrium where the carbon content is dropping slowly but at no time is there a great excess of oxygen over that required for the chemical balance. The relation of carbon to oxygen in the metal is shown in Figure 15-40, where are plotted the results of analyses

FIG. 15-40. Relationship between carbon and oxygen in basic open-hearth steel. (After Fetters and Chipman).

taken from a large number of open-hearth heats during the finishing period. The effect of temperature on the carbon-oxygen reaction is small but is such that more carbon and oxygen may exist together at higher temperatures.

Frequently it is necessary to stop the progress of a heat because the carbon content may be dropping too rapidly for accurate control by chemical analysis or because the drop in carbon content must be stopped until other control analyses may be completed. Holding the carbon content at a given level, or "blocking the heat," is accomplished by adding to the metal bath sufficient deoxidizing agent to lower its oxygen content below the amount required for reaction with carbon. These deoxidizers may be special-quality pig iron or one of numerous ferroalloys which contain elements having a high affinity for oxygen. Blocking the heat is only a temporary measure, and the effect of the blocking agent is often cancelled by diffusion of oxygen from the slag before the heat is tapped. In this case, the oxygen

content may again be estimated from the carbon analysis, provided the carbon-oxygen reaction has begun again to some degree.

The direct use of oxygen (or compressed air) for rapid elimination of carbon from the steel bath was discussed briefly in Section 7 of this chapter.

Chemistry of Steel in the Ladle and Molds—The chemistry of ladle additions is a subject of great importance, as indicated by the objects to be accomplished:

- (1) Final deoxidation to the point desired.
- (2) Final adjustment to the composition desired.
- (3) Final additions to develop special properties in the product, such as resistance to corrosion or aging, or machinability.

Every addition made is subject to reaction with the metal itself or some other element or compound in the metal that may be added to it. For this reason, ladle additions must be correlated with the treatments the heat has received in the furnace in order to produce the many types and grades of steel. In general, elements which are not oxidizable, such as copper or nickel, may be added to the furnace before tapping. Large amounts of deoxidizers, or easily oxidizable elements, are not commonly added to the furnace because of excessive losses due to the highly oxidized condition of the slag, and because of the danger of phosphorus reversion.

The degree of deoxidation obtained through ladle additions will depend on the kind and amount of deoxidizer used, as shown in Figure 15-41, which compares the effectiveness of several elements by showing the relative amounts in equilibrium with dissolved oxygen.

The additions which are made to molds are primarily for the purpose of obtaining the type of solidification desired. Small amounts of aluminum, usually a few ounces per ton of steel, may be used to control the rimming action in making rimming steel, while either ferrosilicon or aluminum are employed for control of the solidification of semikilled steels. In the manufacture

FIG. 15-41. Relative deoxidizing power of some of the elements. (From "Basic Open Hearth Steelmaking," published by AIME.)

FIG. 15-42. Effect of temperature on the deoxidizing power of silicon. (Same source as Fig. 15-41.)

of some killed steels the deoxidation may be completed with aluminum during the filling of the mold. On some grades of steel which may be difficult to rim, "rimming agents," of which sodium fluoride is the chief example, are used to promote gas evolution. In general, mold additions are kept quite small because the opportunity for good mixing is not great and the pouring temperature is too low to insure the melting of large amounts of cold material.

NONMETALLIC INCLUSIONS

The nonmetallic inclusions which are normally found in steel may be traced to one of the following sources:

Refractory Material—Since the liquid metal is in contact with refractories until it is teemed into the molds, there is a possibility that small fragments of refractory material may be broken away or removed by erosion or reaction and enter the metal. Usually the particles are large and, unless trapped, will rise rapidly to the surface of the metal in the ladle or mold. As a result, non-metallic inclusions from this source are found only infrequently.

Oxygen and Sulphur—These elements are responsible for most of the nonmetallic inclusions, and only by their complete elimination from the process would it be possible to produce steels without inclusions.

While the steel composition is a factor, it is generally true that sulphur is quite soluble in steel at all temperatures above the melting point so that if sulphur is present, sulphide inclusions will not form until the steel solidifies, and thereby will be trapped in the ingot.

This is likewise true of oxygen in the case of steels which are not deoxidized. When strong deoxidizers, such

as silicon or aluminum, are added to the ladle, their oxides are formed with the dissolved oxygen in the steel. It is probable that the majority of these oxides will float to the top of the ladle and be eliminated. However, the deoxidizing power of most deoxidizers increases as the temperature falls so that oxides are continually forming as the temperature drops to the solidification point of the steel. This effect is shown for silicon in Figure 15-42.

The rate at which particles will rise from liquid steel is indicated by Stokes' law:

$$V = K \cdot \frac{2}{9\eta} \cdot r^2 g (d' - d)$$

where

V = Rising velocity

K = a constant

r = Radius of the particle

g = Acceleration due to gravity

d' and d = Density of liquid steel and inclusion, respectively

η = viscosity of liquid steel

The most important variable in this expression is " r ," the radius of the particle which should be large for rapid rates of rise. The most desirable deoxidizer would consequently be one which produces a liquid oxide, since liquids possess the ability to coalesce and form larger particles. Nevertheless, it will be evident from the above discussion that inclusions are inherently a part of steel as made by commercial processes, and it is their location and distribution throughout the ingot which will determine whether or not they are harmful.

SECTION 9

OPERATION OF AN ACID OPEN-HEARTH FURNACE

Materials for the Charge—In acid open-hearth practice, the initial charge consists normally of cold pig iron, or cold pig iron and scrap. No ore can be added with the

charge as in the basic process, for the iron oxide, being a base, would combine with the acid lining and rapidly destroy the bottom and banks. For the same reason the

melting of scrap alone would be bad practice for its oxidation products would have a similar detrimental effect. Hence, the use of hot metal (molten pig iron) to supply the whole of the pig iron part of the charge is impracticable, for it would necessarily have to be added after the scrap was hot and had been considerably oxidized.

The proportion of scrap to pig iron may vary over wide limits. As previously pointed out, Siemens originally used no scrap, and as ore was added to the pig iron after melting to hasten oxidation, his process was called the pig and ore process. Later, the Martin brothers used scrap with only enough pig iron to make the melt have the carbon content desired in the finished steel. As they used no ore, their method of working was called the pig and scrap process. The modern method, in which a charge of pig and scrap is melted, then "ored down" or "pigged up" as required, may be looked upon as a combination of these two methods. In it, the relative amounts of pig iron and scrap in the charge are controlled largely by plant and market conditions; that is, the supply and relative cost of these materials. If both are available, then the only thing considered in proportioning the charge is the carbon content it is desired the charge should have when melted. In times of extreme shortages of pig iron, substitutes such as Mexican graphite, silicon carbide, or silicon-steel scrap may be used with an increased scrap charge. Coke cannot be used because of its high sulphur content.

Grade of Scrap and Iron for the Charge—Only a trace of the phosphorus and none of the sulphur are eliminated in the acid open-hearth process. Indeed, the finished steel may contain a slightly higher percentage of both of these elements than the average of the charge. This increase is due to the fact that, while the weights of the sulphur and phosphorus remain practically constant, the weight of the metallic bath may be decreased appreciably, owing to losses through oxidation of iron and metalloids. In addition, the bath is likely to absorb some sulphur from the flame. Consequently, great care must be exercised to see that the average sulphur and phosphorus content of the charge is somewhat below that required in the finished steel. Silicon, manganese, and carbon are oxidized very readily in this process; consequently, require less consideration in the selection of materials. The specifications for acid open-hearth pig iron usually call for a silicon content under 2.00 per cent, manganese 1.00 to 2.00 per cent, and phosphorus and sulphur under 0.03 per cent. In steel for some grades of sheets, the phosphorus content may be somewhat higher, under 0.06 per cent being satisfactory. It is an easy matter, either at the blast furnaces or at the steel works, to secure a representative sample of any lot of pig iron, and its selection offers little difficulty. But it is almost impossible to secure a representative sample of the scrap for analysis; hence, the scrap must be selected by inspection and with much care and judgment. For example, in order to produce a steel with a phosphorus and a sulphur content each under 0.05 per cent, such scrap as tubes, pipe, Bessemer rails, and castings from unknown sources must be avoided. The size of the scrap is also of some importance. Unless the proportion of pig iron is large, light scrap makes it difficult to get a full charge into the furnace. Besides, light scrap is excessively oxidized in melting, unless extraordinary precautions are taken in charging. This oxidation of the iron not only decreases the yield, but the resulting iron oxide also combines with the siliceous lining and rapidly fluxes out the bottom and banks of the furnace.

Manner of Charging—A few small and isolated furnaces still may be charged by hand, but in the main all the larger furnaces will be charged by machine. As to

the order in which the pig iron and scrap are charged, it is unimportant which is charged first if the scrap is heavy or makes up less than half of the total charge. But if the scrap is light, many prefer to charge it ahead of the pig iron which, being spread out on the top, tends to shield the scrap from direct contact with the flame and to prevent its being oxidized excessively. Others make a practice of charging part of the pig iron on the bottom and part on top of the scrap. The pig iron on top melts first and, trickling down over the scrap beneath, the silicon and carbon it contains react with iron and manganese oxides as soon as formed, thus insuring that the latter do not come in contact with the bottom or banks. The added protection afforded by a little pig iron on the bottom is obvious, and is a great advantage. It not only will increase the yield but also will save much repairing of the bottom. As soon as the liquid basic oxides of iron and manganese come in contact with the acid oxides of silicon in the lining, silicates of these oxides are formed and become slag. Then, not only are the banks rapidly eroded away, but also the iron and manganese oxides are neutralized and lose their power of oxidizing and neutralizing the metalloids in the pig iron.

Melting—As soon as the furnace has been charged, the fuel, which is usually partly or wholly turned off during the charging, is turned on full, and the flame is reversed every twenty to thirty minutes in order to raise the temperature and melt down the charge as quickly as possible. The heat usually requires little attention during the first part of this period, so the time generally is occupied in preparations for tapping. The steel ladle requires a new nozzle and a new stopper, and the ladle and cinder pits must be cleaned out—duties performed by men on the pouring floor. On the charging floor the second helper cleans and repairs the steel runner, sets it in place, and sees that it is thoroughly dried; procures, or has brought to the furnace, the ferromanganese, ferrosilicon, anthracite coal, and other deoxidizers and recarburizers required. From four to five hours are required to melt the charge. Toward the end of this period, the first helper, or melter, will keep a close watch upon the action of the heat. If the charge contained a larger proportion (over half) of pig iron, especially if the iron carries a high silicon and low manganese content, the slag formed will be very thick or viscous and, in order to hasten the process and increase the yield, it is necessary to add a little ore or lime. Great care must be used in adding lime, to prevent the banks from being destroyed. On the other hand, if the charge was composed chiefly of scrap, or the pig contained a low percentage of silicon, it may be advisable, in order to save the banks and bottom from excessive scorification, to add some sand, old bricks, or other siliceous material.

Adjusting Conditions After Melting—After the charge has melted completely, the heat, if handled properly, should and usually does contain about 20 to 40 points (hundredths of a per cent) more carbon than is required in the finished steel. Some melters prefer to have the heat melt with a carbon content of more than one per cent in all cases, but for soft steels this practice will not improve the steel and may cause additional labor.

If the charge was made up largely of a low-silicon pig iron and the heat was given proper attention during the melting period, practically all of the silicon and manganese will have been oxidized and neutralized, forming the slag. This slag, at first black in color, is normally made up of about 50 per cent of bases, principally iron and manganese oxides, and about 50 per cent of acids, principally silica. Such a slag tends to be

self adjusting in that the slag will tend to retard the elimination of silicon and carbon from the metal, if the silica content of the slag is increased, whereas if the iron and manganese contents be increased, silica will be absorbed from the furnace banks. Where the melting has been such that considerable oxidation may have occurred, the first slag may be sufficiently oxidizing to complete the elimination of carbon without the necessity of ore additions. This first slag tends to adjust itself as follows: As the temperature rises, the carbon in the bath reduces iron oxide in the slag, causing the slag to grow lighter in color. Also, the slag gains more manganese oxide so that the color changes are black to brown to greenish yellow to a light green color, tinted according to the manganese it contains. These color changes are still sometimes used to follow the course of the heat. However, more recently there have been developed slag fluidity measurements which, in conjunction with temperature measurements, give a more accurate picture of the condition of the slag. The measurement is based on the fact that the silica content of the slag greatly affects its fluidity and this fact can be used to determine the need for additions to the slag to cause it to be more or less oxidizing to the bath. The changes, which the slag tests indicate are necessary, may be made by lime or ore for more oxidizing conditions or by carbon and the regulation of fuel input when the oxidizing power of the slag is too great.

Working the Heat—The problem now before the melter is to reduce the carbon content as rapidly but controllably as possible, and at the same time get the metal heated up to a temperature that will permit the heat to be tapped and teemed satisfactorily. In order to determine the carbon content of the bath, a fracture test of the metal may be taken, but more often an instrument such as the "Carbometer," or "Carbanalyzer" or chemical analysis is used.

If the metal appears to be too cold, attempts are made to raise its temperature by burning more fuel and reversing the flame frequently, before any necessary ore is added. If the carbon is relatively high and the bath is quiet and sufficiently hot, a few lumps of ore are added to start a boil. After this ore has had time to react with carbon, more ore may be added, but this is not done so rapidly that a large excess of iron oxide is created in the slag, as this would result in erosion of the banks of the furnace and cause excessive slag volume.

If, by virtue of a large ore addition, the carbon content becomes lower than desired, it may be restored by adding pig iron to hold the carbon at the desired level until the tapping temperature is reached. Thus, by frequent sampling of the bath and treating it as required, the carbon content and the temperature will be so adjusted that the heat may be tapped. Low carbon heats, under 0.30 per cent carbon, may be normally worked down to a carbon content of 0.10 per cent to 0.12 per cent and recarburized to the desired composition by ladle additions, and some melters prefer to do this. However, especially in the case of higher carbon heats, it is customary to "block" the heat with ferro-silicon at the required carbon content. Since no phosphorus is removed in this process, the addition of large amounts of pig iron or spiegel for recarburizing is inadvisable, unless low-phosphorus pig iron is available, lest the phosphorus content be increased beyond the limit allowed. Therefore, medium- and high-carbon heats are usually "caught on the way down."

Finishing Acid Open-Hearth Steel—During the last hour the heat is in the furnace, little ore is added so that the carbon content may drop slowly and under con-

trol to the desired value for tapping. However, the slag must not become too depleted in iron oxide, for if the temperature is high, as in the case of low-carbon heats, some silica may be reduced and the silicon content of the steel will be increased. This condition will be indicated to the melter by a cessation of boiling and by an increase in the viscosity of the slag. It may be prevented by the addition of a small amount of limestone, which will decrease the viscosity of the slag and make available iron oxide by combining with the silica of the iron silicates. In Table 15—VI are shown the compositions of three finishing slags illustrative of the widest variations to be expected under normal conditions. Only the significant components are given.

Table 15—VI. Composition of Acid Open-Hearth Slags (Per Cent)

Constituent	Heat Number		
	1	2	3
SiO ₂	54.25	52.06	55.60
FeO	25.87	20.38	28.90
MnO	11.27	20.52	10.23
P ₂ O ₅	0.045	0.035	0.022
Al ₂ O ₃	3.28	3.07	4.16
CaO	5.37	4.35	0.70
MgO	0.12	Trace	0.12

When the temperature has been raised to the proper level and the slag is in the proper condition for tapping, the heat may be blocked or allowed to work slowly down to the required carbon content. At this time, additions to adjust the amount of alloying elements may be made. If the charge for the heat has been selected with care, the preliminary analysis, taken when the charge was completely melted, will have shown that the phosphorus and sulphur specifications will be met. However, if error or lack of satisfactory control of raw materials causes either the phosphorus or sulphur content, or both, to be too high, the heat must be rejected in the case of most steel foundries, or applied to an order with higher specifications for these elements, for there are no corrective measures that can be applied to reduce their contents.

Tapping—When ready, the heat is tapped by methods described for basic furnaces.

Additions to the Heat—In the acid open-hearth process, additions to the heat are made both in the furnace and in the ladle. In making high-carbon heats in which the carbon is caught on the way down, most of the additions, including ferromanganese and ferro-chromium, are added in the furnace, as well as unoxidizable additions such as copper, nickel, and molybdenum compounds. In making medium and low-carbon steels, adjustments in carbon content are made in the ladle, preferably with anthracite coal of about pea size. To facilitate the addition, the coal usually is contained in paper bags, each holding a known weight. Ferromanganese also may be added in the ladle, for which purpose it usually is crushed to pass a 2-inch screen. Additions made to the steel in the ladle also include such materials as ferrovanadium, ferrosilicon, ferrotitanium, and aluminum. All ladle additions should be completed before much slag begins to flow from the furnace. Additions to the heat during the pouring of ingots usually are confined to aluminum.

Teeming—The proper manufacture of an acid open-hearth steel heat leads to tapping temperatures of the order of 3000° F. For the manufacture of small and

intricate castings where many molds must be poured, such a temperature may be necessary at the start of the pour in order that the last molds may be filled. In pouring large castings, however, a temperature of this magnitude may be too high for what has been established as good practice. Pouring temperatures and rates will depend on mold sizes and the use for which the castings are intended. Small molds are usually filled by "hand shanking" whereby sufficient metal for one mold is taken from the large ladle in a small hand ladle for pouring. Larger molds are filled by the conventional ladle with stopper and nozzle.

The temperature and rate conditions mentioned above also apply in the pouring of ingots whose sizes may vary from 500 pounds for small forgings to as much as 400,000 pounds for very large forgings. The types of pouring employed are top pouring, bottom pouring, and basket or tun dish pouring, which already have been discussed in Section 5.

Preparation of the Furnace for the Next Charge—Efficient operation of the furnace requires that the next heat be charged with little delay after tapping. This is possible only if the furnace is kept in good condition from day to day and heat to heat; consequently, as soon as the heat is out of the furnace, the melter inspects the interior carefully. Steel remaining in low places on the hearth is removed by rabbling and holes are filled with bottom sand. All steel and slag are cleaned from the tapping hole, which then is closed in the same manner as described previously. While the taphole is being made up, the banks are repaired by shoveling sand on them and fritting it into place. This work requires about an hour if the banks can be rebuilt with one layer of sand. If the banks have been eroded badly, the sand must be applied in two coats and about forty-five minutes are required for each coat. As soon as this repair work is completed, charging of the furnace may begin.

SECTION 10

CHEMISTRY OF THE ACID OPEN-HEARTH FURNACE

Chemistry of Melting—The elimination of silicon, manganese, and carbon is effected in two stages corresponding to the melting and boiling of the heat. Analyses show that during melting nearly all of the silicon and manganese and a part of the carbon are oxidized. Since no ore is charged in the acid process, the only source of oxygen for oxidation during this stage is the furnace gases, which consist of the products of combustion of the fuel and any excess air which may have leaked into the furnace. Carbon dioxide, water vapor, and oxygen in the furnace atmosphere will oxidize iron rapidly above a red heat. The extent to which the oxidation will proceed will depend on the proportions of these gases and the gaseous products of the oxidation in the atmosphere, and the temperature. This action is confined to the surface until the fusion point is reached. When the melting point of the iron oxides is reached, they begin to flow off, thus leaving the metal beneath exposed to further oxidation. This action applies to the scrap only, because the melting point of the pig iron is about the same or lower than that of the oxide.

Purifying Reactions—The fact that the melting point of the pig iron is lower than that of the scale is a fortunate circumstance, for otherwise the liquid scale would trickle to the bottom of the furnace and there react with the silica hearth to form a slag. With the pig iron in a molten state on the bottom of the furnace, these oxides of iron react with the metalloids, removing them from the bath and giving up some of the iron contained in the iron oxides.

After the greater portion of the silicon and manganese has been oxidized, a small part of the phosphorus may be oxidized; but later, when the slag becomes higher in silica, the phosphorus compounds will be reduced, returning the phosphorus to the metal. Therefore, seldom more than traces of phosphorus can be removed from the charge; in fact, the phosphorus content may increase slightly by virtue of the removal of the other metalloids.

Elimination of Carbon During the Melting Period—If the melting could be effected instantaneously, very little carbon would be oxidized until after the silicon and manganese were eliminated. But since melting takes place gradually, a part of the pig iron coming in contact with the highly oxidizing basic slag, both being in the liquid state, loses its metalloids, including carbon, quickly; consequently the percentage of carbon in the

bath, immediately after melting is complete, will be considerably lower than the average of the charge. While the amount of carbon thus oxidized cannot be predicted accurately, melters are quite successful in properly proportioning pig iron and scrap to the condition of the furnace and method of charging, to have the heat melt near the carbon content desired for proper finishing.

Chemistry of the Boil—By the time the charge has melted completely, a substantial portion of the silicon and manganese will have been oxidized to form a slag. If the melting has been rapid, there may not have been enough oxidation of the scrap to start a boil, so ore must be added. On the other hand, if the melting has been slow, enough oxidation may have occurred for the boil to be completed without the use of ores. If the carbon content is low, the melter will first attempt to increase the temperature of the bath by increasing the fuel rate and reversing the flame more often, but if the carbon content is high, for example fifty points over the content desired, the feeding of ore may begin as soon as the temperature is sufficiently high. If the temperature is too low when ore is added, its action is delayed and is too violent when it occurs. The mechanism of metalloid elimination involves the same chemical reactions as those discussed under basic practice. The ore additions are made gradually in order to keep the boil under control and to protect the banks of the furnace.

Chapter 16

ELECTRIC FURNACE STEELMAKING

SECTION 1

DEVELOPMENT AND PRESENT STATUS OF ELECTRIC MELTING FURNACES

Numerous types of furnaces utilizing electric current as the source of heat have been developed by a large number of investigators, but relatively few types have survived as practical tools for steelmaking.

Methods of Electric Heating—Electric current can be used for heating in only two ways: (1) by utilizing the heat generated in electrical conductors by their inherent resistance to the flow of current; and (2) by utilizing the heat radiated by the electric arc.

Two general methods of heating by resistance are possible: (a) the indirect method in which the charge is heated by radiation and conduction from separate resistors through which the current is passed, and (b) the direct method in which the current is passed through the metal charge or bath itself. The indirect method of resistance heating for steel-melting operations is not practicable, for many reasons. The direct method in which high-voltage, low-amperage current is transformed to low-voltage, high-amperage current that

passes through the bath or charge is successfully employed. The bath in this latter method acts as the secondary circuit for the current which is generated from a primary circuit by induction; the method being known, therefore, as induction heating.

Likewise, arc heating may be applied in two general ways: (1) The arcs may be made between electrodes supported above the metal in the furnace, which thus is heated solely by radiation from the arc. This method is known as indirect-arc heating. (2) The arcs may be made between the electrodes and the metal. In this second method, known as direct-arc heating, the current must flow through the bath, so that the heat developed by the electrical resistance of the metal, though relatively small in amount, is added to that radiated from the arcs. This plan makes it possible to use two types of furnaces, namely, those with a non-conducting bottom, and those with a conducting bottom. The latter type has not been successful for practical steelmaking use.

Table 16—I. Classification of Electric Furnaces for Making Steel According to Principles of Heating Employed.

Indirect —The current is passed through a special resistor to generate heat, which is used to heat the charge by radiation, convection and conduction. Such furnaces are used for heat treating but not for melting steel.	
Resistance Furnaces	Using current from low voltage transformers. Not successful for melting steel.
Direct —The current passes through the material to be heated.	[Low frequency—Using a core transformer with the bath forming the secondary circuit.
	Induction High Frequency Coreless Induction. Current of high frequency is passed through a coil surrounding a crucible containing the charge.
	Direct Current Arc —Not used.
Indirect or Independent Arc —The bath is heated by an arc or arcs above it.	Single phase {rolling furnace with horizontal electrodes. furnaces for special purposes.
	Alternating Current Two phase {Straight arcs. } not used. Deflected arc.
	Three phase {Straight arcs. } not used. Repel-arc.
	Furnaces may be stationary, oscillating, or rolling.
Arc Furnaces	Series Arc. Current arcs from one electrode to the bath, passes through the bath, and arcs to another electrode. {Single phase Two phase Three phase
Direct Arc —The current arcs from electrode to bath.	
Combination Arc and Resistance —Use the arc and resistance of refractory bottom material for heating charge.	Single Arc. Current arcs from one electrode to the bath, passes through the bath, and out through an electrode in the bottom of the furnace. {Single phase Two phase Three phase

HEAT No. 3

ELECTRODES HAVE BEEN LOWERED THROUGH THE OPENINGS IN ROOF, POWER HAS BEEN TURNED ON AND THE CHARGE IS BEING MELTED AND STIRRED TO PRODUCE THE DESIRED GRADE OF STEEL

In furnaces with a non-conducting bottom, the path of the current is through one electrode and thence through the arc between the foot of the electrode and the bath, then through the bath and up through an arc between the bath and an adjacent electrode, completing the circuit through this second electrode. Path of the current through furnaces with conducting bottoms would be from the electrode or electrodes above the bath, through the arc into the bath and thence out of the furnace through an electrode forming part of the bottom in contact with the bath.

Table 16—I presents a listing of basic principles of electric heating which also will serve as a basis for classifying electric furnaces as to type. From among the many types listed therein, only two appear to have been able to stand against practical tests and competition as suitable for melting steel; these are the direct-arc furnace (series arc) originally developed by Heroult, and the high-frequency coreless induction furnace, which are discussed in Sections 2 and 5, respectively, of this chapter.

HISTORICAL DEVELOPMENT OF ELECTRIC MELTING FURNACES

It has been said that arc-type furnaces had their beginning in the discovery of the carbon arc by Sir Humphrey Davy in 1800, but it is more proper to say that the practical beginning of the art was the work of Sir William Siemens, who in 1878 constructed, operated and patented furnaces operating on both the direct-arc and indirect-arc principles.

At this early date, the availability of electric power was limited and its cost high; also, carbon electrodes of the quality required to carry sufficient current for steel melting had not been developed. Thus, the development of the electric melting furnace awaited the expansion of the electric-power industry and improvements in carbon electrodes.

Direct-Arc Furnaces—The first successful commercial direct-arc steelmaking furnace was placed in operation by Heroult in 1899, and the first shipment of electric steel was a carload of bars from Heroult's plant at La Praz to the firm of Schneider and Company at Creusot, France, on December 28, 1900. The Heroult patent, stated in simple terms, covered single-phase or multi-phase furnaces with the arcs in series through the metal bath.

This type of furnace, utilizing three-phase power, has been the most successful in the production of steel. During recent years, many large-capacity furnaces with 20-foot diameter shells holding an average charge of 185,000 pounds were placed in successful operation. During 1954, two furnaces designed for a maximum charge of 200 tons were installed; these furnaces have an inside diameter of 24½ feet and a hearth depth of 3 feet, 9 inches. Such units have been made possible by the increased availability of electric power, large graphite electrodes, and improved refractories, along with better furnace design and melting practices. These factors will be discussed in detail later. A typical large modern unit is shown in Figure 16—1.

Simultaneous with and subsequent to Heroult's success with the direct-arc principle, many investigators abroad directed their attention to developing furnaces employing the same principle. However, in this country, there were no developments along arc-furnace lines until the first Heroult furnace was installed in the plant of the Halcomb Steel Company, Syracuse, New York, which made its first heat on April 5, 1906. This was a single-phase, two-electrode, rectangular furnace of four tons capacity. Two years later a similar but smaller

furnace was installed at the Firth-Sterling Steel Company, McKeesport, Pennsylvania, and in 1909, a 15-ton, three-phase furnace was installed in the South Works of the Illinois Steel Company, now a part of the United States Steel Corporation, in Chicago, Illinois. The latter was, at that time, the largest electric steelmaking furnace in the world, and was the first round (instead of rectangular) furnace. It operated on 25-cycle power at 2200 volts and tapped the first heat on May 10, 1909.

The foregoing furnaces all were used for making steel for ingots. The first electric furnace for the production of steel for commercial castings was that of the Treadwell Engineering Company, Easton, Pennsylvania. It was a single-phase, two-electrode furnace of two tons capacity, designed along the lines of the Halcomb and Firth-Sterling furnaces. It was operated first in August, 1911.

About the same time, the General Electric Company began to experiment with the design of direct-arc electric furnaces, with the view of developing a market for electrical equipment required for their operation, and built three or four units. Other furnace designs followed: the Snyder, Ludlum, Vom Baur, Booth-Hall, Moore, Green, Swindell, and Volta, the last-named being of Canadian origin.

Indirect-Arc Furnaces—The first work on indirect-arc furnaces was done by Stassano, in Italy. His design consisted of a vertical, cylindrical shell, with three electrodes spaced 120 degrees apart and entering the furnace just above the bath. A furnace of this design was installed in the plant of the Clark Equipment Company, Buchanan, Michigan, in 1911.

About the beginning of World War I, Rennerfelt of Sweden developed an indirect-arc furnace with two horizontal electrodes and one vertical electrode, so connected electrically that the arc was "blown" down on the charge or bath, and the horizontal electrodes were arranged to tilt downward so that they could arc directly on the bath.

None of the indirect-arc furnaces came into very great use because maintenance was difficult and power consumption was high.

The Induction Furnace—Another type of electric melting furnace, used to a certain extent for melting high-grade alloys, is the high-frequency coreless induction furnace (Figure 16—2), which gradually replaced the crucible process in the production of complex, high-quality alloys used as tool steels. It is used also for remelting scrap from fine steels produced in arc furnaces, melting chrome-nickel alloys, and high-manganese scrap.

The induction furnace had its inception abroad and first was patented by Ferranti in Italy in 1877. This was a low-frequency furnace. It had no commercial application until Kjellin installed and operated one in Sweden. The first large installation of this type was made in 1914 at the plant of the American Iron and Steel Company in Lebanon, Pennsylvania, but was not successful. Some other low-frequency furnaces, however, have operated successfully, especially in making stainless steel.

A successful development using higher-frequency current is the coreless high-frequency induction furnace. The first coreless induction furnaces were built and installed by the Ajax Electrothermic Corporation, who also initiated the original researches by E. F. Northrup leading to the development of the furnace. For this reason, the furnace is often referred to as the Ajax-Northrup furnace.

The first coreless induction furnaces for the production of steel on a commercial scale were installed at Sheffield,

FIG. 16-1. A large, modern, three-phase Heroult electric-arc furnace.

FIG. 16-2. Dual installation of coreless electric induction melting furnaces, with control panel in background. (Courtesy, Allis-Chalmers Mfg. Co.)

England, and began the regular production of steel in October, 1927.

The first commercial steel furnaces of this type in the United States were installed by the Heppenstall Forge and Knife Company, Pittsburgh, Pennsylvania, and were producing steel regularly in November, 1928. Each furnace had a holding capacity of 600 pounds and was served by a 150-kva motor-generator set transforming 60-cycle current to 960 cycles. The crucibles were monolithic, 6 inches in diameter, and 36 inches in depth. Time of an ordinary heat was 55 minutes. The coreless type of induction furnace normally operates on alternating current at a frequency of approximately 1000 cycles, produced by a motor-generator set of special design with the power transmitted over co-axial cables to the primary coil of the furnace. Recently, mercury-arc rectifiers, which have the advantage of higher efficiencies over motor-generator sets, have been developed to supply the high-frequency power. Some details of operation of this type of furnace are given in Section 5 of this chapter.

The primary coil of the coreless induction furnace is constructed of water-cooled copper tubing, positioned toward the inside of the furnace shell but covered with a layer of refractory material. The shell must be constructed of non-conducting materials, since the high-frequency power applied to the primary coil otherwise would induce current in the shell as well as the charge, and generate heat in the former. When operating, the high-frequency power applied to the primary coil creates a magnetic flux which passes through the charge, and the charge acts as the secondary winding of a transformer having a single turn. This induced current melts the charge by the heat developed due to the electrical resistance of the charge.

Commercial use of the high-frequency furnace for melting is not extensive in the steel industry. Those in use are small in size, ranging in capacity from about 500 pounds to 2,000 pounds. The largest one in the United States is of four-ton capacity and has for a power source a 1200-kilowatt motor-generator set.

Due to the time required to prepare the scrap and place it in the furnace, the usual installation consists of two furnaces for each generating unit. Thus, one heat can be melting while the next is being prepared. The finished heat can be disconnected from the power source and the furnace used as a ladle and carried by a crane to the molds for pouring, while the second furnace is connected to the power system.

Electric Reduction Furnaces—Electric reduction furnaces are used for smelting ores in the production of ferromanganese, ferrosilicon, ferrochromium, and so on. These furnaces differ from the steelmaking furnaces in that production is continuous, as in a blast furnace; the charge is placed in the furnace at the top and the molten product tapped near the bottom. They are designed either as single-phase or three-phase units.

In the single-phase units, a single carbon electrode is suspended in the center of the furnace, with the carbon bottom of the furnace serving as the second electrode. This is an example of a furnace with a conducting bottom. In the three-phase furnaces, the three electrodes are spaced as in the arc furnace and are buried in the charge. These units normally have an open top, and the charge either is shoveled in or introduced by chutes. The electrical load on this type of furnace differs from that on the arc furnace used for steelmaking. Since charging is continuous, the load is fairly steady, and the power factor can be maintained around 90 per cent. The voltages used are lower than in the arc furnaces, and the current density greater. These requirements necessitate

a careful design of the secondary circuits to keep reactance to a minimum. For some products, and on 25-cycle systems, units of electrical capacities up to 18,000 kva have been designed.

Furnaces of Special Design—There have been other types of furnaces designed that are worthy of mention. The Hering furnace was a conventional unit except that the bath was deeper than usual and the hearth contained one or more resistance tubes at the bottom which served as water-cooled electrodes. Molten metal was required for the first charge, and only two-thirds of the heat was tapped. The effect of the current flowing through the molten metal in the resistor tubes was to pinch off the column of metal and eject it from the tube. The furnace had no commercial application.

Another furnace of European design was a combination of open-hearth and electric-arc furnace principles. Still another was a combination of low-frequency induction furnace and pneumatic converter, the tuyeres of the latter being equipped so that a reducing gas might be introduced into the furnace.

Field of Application of Electric-Arc Furnaces—In the preceding section, it was pointed out that the electric-arc furnace for steelmaking first was introduced into the United States in 1906. The real expansion of this phase of the industry, however, has been more recent, with respect to both basic-lined and acid-lined electric-arc furnaces. The first development was due to the wide use of the SAE low-alloy steels. Then came the development and expanding use of higher alloy and stainless steels, which have been largely responsible for the more recent increasing use of basic-lined electric-arc furnaces in the steel industry.

The steel-casting industry found that acid-lined electric-arc furnaces were well qualified to meet their needs in regard to control of operations and quality of product. This has been the important factor in the growing use in foundries of this type of furnace.

Both the acid and basic processes for making steel in electric furnaces were used extensively during World War II, and production has continued at a high level. The basic process, especially, is in a good position to maintain a high production rate because of its ability to use both high-alloy steel scrap, lower grades of alloy scrap, and plain-carbon steel scrap in making steels that will meet rigid chemical, mechanical-property and cleanliness requirements.

The basic process, for which the electric-arc furnace utilizes a basic bottom of magnesite or dolomite and sidewalls and roof of either basic or silica brick, accounts for practically all of the electric-furnace steel produced in ingot form. Furnaces of this type usually are found in integrated steel works having installations for making steel by other processes also, where facilities already are available for stripping the ingots, heating them, and rolling or forging them to the desired size and shape. Such integrated plants make possible the utilization of the cold-melt process or one of the hot-metal methods such as duplexing, triplexing, or the refinement of molten open-hearth steel by special slags which can be prepared and removed more conveniently in the electric furnace than in the open hearth.

The acid electric furnace, with an acid bottom of ground ganister and silica-brick sidewalls and roof, seldom is used outside of steel foundries and forging shops. Straight-carbon, low-alloy and some high-alloy steels can be made by the acid process.

The importance of electric furnaces as steelmaking units in ingot-producing plants in the United States is indicated by the annual tonnages shown in Table 16—II, which also shows the increasing trend in production of

Table 16—II. Annual Production of Electric-Furnace Steels⁽¹⁾
(Steel Ingots and Steel for Castings—Net Tons)⁽²⁾

Year	Electric-Furnace Steel		Total All Processes, Including Electric		Percentage Represented by Electric-Furnace Steel	
	Capacity	Production	Capacity	Production	Capacity	Production
1954	10,448,640	5,436,054	124,330,410	88,311,652	8.4	6.2
1953	10,232,450	7,280,191	117,547,470	111,609,719	8.7	6.5
1952	8,232,850	6,797,923	108,587,670	93,168,039	7.5	7.3
1951	7,554,610	7,142,384	104,229,650	105,199,848	7.2	6.8
1950	6,871,290	6,039,008	99,392,800	96,836,075	6.9	6.2
1949	6,112,870	3,782,717	96,120,930	72,978,176	6.4	4.9
1948	5,396,750	5,057,141	94,233,460	88,640,470	5.7	5.7
1947	5,076,240	3,787,735	91,241,250	84,894,071	5.6	4.5
1946	5,500,290	2,563,024	91,890,560	66,602,724	6.0	3.8
1945	5,455,890	3,456,704	95,505,280	79,701,648	5.7	4.4
1944	5,350,880	4,237,699	93,652,290	89,641,600	5.7	4.7
1943	4,554,980	4,589,070	90,292,660	88,836,512	5.0	5.2
1942	3,737,510	3,974,540	88,569,970	86,031,931	4.2	4.6
1941	2,586,320	2,869,256	84,152,292	82,839,259	3.1	3.5
1940	1,882,630	1,700,006	81,619,496	66,982,686	2.3	2.5
1939	1,725,086	1,029,067	81,828,958	52,798,714	2.1	1.9
1938	1,490,858	565,627	80,185,638	31,751,990	1.9	1.8
1937	1,326,788	947,002	78,148,374	56,636,945	1.7	1.7
1936	1,147,221	865,150	78,164,300	53,499,999	1.5	1.1
1935	1,053,370	606,471	78,451,930	38,183,705	1.3	1.6

⁽¹⁾ From Annual Reports of American Iron and Steel Institute.

⁽²⁾ The figures include only that portion of the capacity and production of steel for castings used by foundries which were operated by companies also producing steel ingots.

electric-furnace steels during the twenty-year period from 1935 through 1954. It should be noted that these figures do not include steel made in electric furnaces by foundries that do not produce ingots. This increase was due to several factors, chief of which was that electric furnaces now are capable of producing a wide range of steels, and no longer are considered as suitable only for making a limited range of high-cost, high-quality steels of special compositions for extremely exacting uses. Originally, electric furnaces were accepted widely as an improvement over the crucible process for producing steels for tools, dies, watch springs, cutlery, and other special requirements, and gradually supplanted that process almost entirely. However, as experience was gained and costs decreased, the field for economical use of electric furnaces expanded greatly.

In addition, acid-lined electric-arc furnaces have sometimes replaced small open-hearth furnaces and pneumatic converters to produce steel for castings.

Although the production of electric-furnace steels during normal times represents only about six and one-half per cent of the total tonnage of ingot steel produced in this country, the electric-furnace products represent practically all of the stainless, constructional alloy, tool, and special alloy steels used in the chemical, automotive, aviation, machine-tool, transportation, food processing and many other important industries. While at the present time the electric-arc furnace cannot compete with the larger open-hearth furnace as to cost in the production of the commoner grades of steel, yet the electric furnace, if operated in a favorable scrap-producing area with favorable power rates, in many cases can produce ordinary carbon steels at costs comparable to, and sometimes less than, open-hearth costs.

General Comparison of Basic and Acid Electric-Arc-Furnace Processes—Following are factors in deciding

which of the two processes is best suited for the economic production of steel to meet demands with respect to grade of steel and its ultimate use. In this comparison, only the acid process involving complete oxidation of the bath, using a single, oxidizing slag, is considered.

1. Slags in the acid process are more siliceous than those in the basic process. Since acid slags do not react with the steel bath to remove phosphorus from the steel, the use of more expensive, carefully selected scrap and other raw materials of low phosphorus content are imperative. Conversely, basic slags do react with and retain phosphorus, and practically all types of scrap and raw materials can be used in the basic electric furnace. It may be mentioned here that sulphur cannot be removed in the acid process, but can be in the basic process, as will be discussed later.

2. Oxidizing action takes place in a shorter time in the acid process and the time required for "working the heat" also is shorter than in the basic process, mainly because of the selected scrap used in the acid furnace as compared with the wide variety of scrap used in the basic process.

3. In the acid process, because of the selected materials making up the charge, a one-slag process predominates, while a multiple-slag practice is used more widely with the basic process.

4. Iron loss is lower with the single-slag acid process than with the multiple-slag basic process because the oxidizing period is shorter, less metal is trapped in the much smaller volume of slag, and, since there is no slagging-off in the single-slag acid process, there is no loss of metal from this source.

The metallurgical differences in the two processes indicate that none of the advantages of one process over the other is sufficient to justify the selection of one or the other process without full consideration of all fac-

tors, such as flexibility and economies. Economy in production combined with adequate performance of finished product have been the determining factors. The result has been the previously mentioned prevalence of the acid process in the steel-castings industry and the basic process in making ingots for rolling.

Cold Scrap vs. Hot Metal—When the first electric melting furnaces were installed in the steel industry, electric power was not available in large amounts. Since the melting operation requires about three times the power that is required by the refining period, it was thought then that the cost of this extra electric power was too high to permit economical melting of cold charges. For this reason, the early installations at Halcomb and Illinois Steel were provided with a separate source of hot metal to provide a molten charge. The former had a tilting 30-ton basic open-hearth furnace and the latter a Bessemer converter department. Later, as more electric power became available, it was recognized that cold melting was feasible.

During World War II, in order to increase production, several installations were made where the practice of using hot-metal charges was revived. The largest installation had nine 70-ton electric furnaces operating in conjunction with tilting open-hearth furnaces to produce steel by a combination method. These door-charged furnaces now operate mainly on cold-melt practice, with some hot metal employed, when available, to aid charging. At the present time, there is no appreciable tonnage of steel being produced in electric furnaces using hot-metal charges. With the advent of new pneumatic processes (Chapter 14), it is possible that these processes may be used to prepare molten charges for finishing in electric furnaces to produce steel.

Advantages of the Electric-Arc Furnace—The increasing number of basic electric-arc furnace installations is evidence that, as steelmaking units, these furnaces provide certain advantages. Among the more important considerations for selecting this method over other steel production methods are the following:

Practically all of the known grades of steel can be produced in the basic electric-arc furnace. The products made include the plain carbon steels of rimmed, capped, semi-killed and killed types, low-alloy SAE-AISI constructional steels, high-manganese steels (up to 14 per cent), high-silicon steels (up to 5 per cent), aluminum steels (up to $4\frac{1}{2}$ per cent), the entire range of stainless steels, super-alloy steels for high-temperature applications, and high-speed and other alloy tool steels.

The basic electric-arc furnace may be selected as the more economical steel producing method when: (1) carbon and low-alloy steel production requirements are insufficient to justify use of the blast furnace—open hearth combination to produce steel, (2) facilities are installed in industrial areas of high steel-scrap availability but at a distance from natural sources of coke, limestone and high-grade iron ores, (3) the nature of subsequent processing is such that steel-production requirements are intermittent or molten metal must be supplied within controlled time limits.

The electric-arc furnace process is capable of producing killed-steel grades with very low residual phosphorus because: (1) the initial charge contains less phosphorus than the charges of steelmaking processes containing blast-furnace iron, and (2) the phosphorus-bearing oxidizing slags of the electric furnace heat may be removed prior to furnace deoxidation and thus avoid phosphorus reversion to the metal.

The greater desulfurizing power of basic electric-arc furnace reducing slags facilitates the production of steels with lower sulphur residuals.

The absence of an oxidizing heat source permits heats that have been deoxidized in the furnace to be held without becoming rapidly reoxidized; this feature, coupled with the ability to use reducing slags, makes it possible to produce steels containing fewer nonmetallic inclusions.

The production of steels alloyed with high percentages of oxidizable metallic elements can be produced more efficiently in the basic electric-arc furnace as such alloying elements or ferroalloys can be added in the furnace under reducing conditions at a high efficiency of recovery and in any amount required. Moreover, with proper slag manipulation, a relatively-high efficiency of recovery of oxidizable elements, such as chromium, manganese, etc., can also be obtained from alloy-steel scrap.

Because it can be tilted to pour off slag, the electric-arc furnace can be operated with slag volumes controlled to a minimum (2 to 4 per cent of the bath weight) and therefore the slag composition can be adjusted and controlled quickly by relatively small additions of slag-making, oxidizing or deoxidizing materials. Therefore, the steel may be treated under oxidizing, reducing or neutral slags, or any succession of such slags.

Under oxidizing slags, the electric furnace with a definite regulation of heat input provides good control of carbon content at melt-down and later while working the heat. Also, the removal of this oxidizing slag, with its comparatively high phosphorus content, limits the amount of phosphorus reversion that can occur by taking a large proportion of this element out of the field of action.

A reducing slag in the basic electric furnace, following the slagging off of an oxidizing slag, makes possible a high degree of refinement of the bath and minimizes loss of alloys by oxidation. Objectionable elements, such as sulphur, can be removed to a high degree after the oxidizing slag has been replaced by a reducing slag. The reducing slag also decreases the oxygen content of the bath to a low value; consequently, relatively few deoxidation products are formed when the final deoxidizers are added because less of the latter are needed. The deoxidation products that are formed have a better opportunity to rise through the steel bath and enter into the slag than would similar substances formed if large amounts of deoxidizers had to be added in the ladle. As a result, relatively few sulphide and oxide inclusions are present in electric-furnace steel, remembering, however, that limited circulation of the bath under this reducing slag necessitates a long refining time.

Disadvantages of the Electric-Arc Furnace—The disadvantages common to the operation of electric-arc furnaces are largely a matter of economics. The cost of auxiliary equipment, operating labor, power, electrodes, and refractories usually are higher than similar costs in the open-hearth and other processes. The costs exclusive of net metallic charge show the electric furnace to be at a disadvantage which can be overcome only partially by faster time of heat and greater efficiency. Individual open-hearth furnaces, in general, are of considerably larger capacity than electric furnaces; the possibility of overcoming the size differential in furnaces of the two types is limited by power problems. Larger electric-arc furnaces require higher voltages to transfer energy economically, and the longer arcs in larger furnaces can cause excessive damage to roof and lining. Peak loads during melt-down periods may increase the difficulties of the power plants which must maintain sufficient power for regular requirements during this same period.

While the foregoing is true with respect to *physical size* from the standpoint of the size of individual heats, the *production rate* of a standard 20-foot shell diameter electric furnace in terms of tons of finished steel produced per hour will compare favorably with 150-ton or larger open-hearth furnaces. Also, in 24-foot, 6-inch

diameter electric-arc furnaces recently installed, heats of nearly 200 tons have been made. Thus, the former advantage of the open-hearth furnace with regard to heat size is being overcome, and other factors (some of them economic and some metallurgical) now are the criteria for comparing the two methods of steelmaking.

SECTION 2

DIRECT-ARC ELECTRIC FURNACES AND AUXILIARIES

Mechanical Parts—All furnaces of the Heroult type are designed to tilt in two directions, the one for pouring and the other for slagging. Heroult furnaces are mounted on toothed rockers which rest on and intermesh with toothed rails. They are tilted by a motor-driven rack-and-pinion mechanism, usually placed underneath the furnace. On large furnaces where a slag-off operation is required, the tilting mechanism is designed to permit movement of a car-mounted slag pot through the foundations to the tapping pit.

Capacity of Furnaces—The inside diameter of the shell determines the capacity of the electric furnace. Many standard sizes have been developed to provide for the different practices and types of scrap used in various shops. Heroult furnaces now are being built by American Bridge Division of United States Steel Corporation in sizes of 7-foot shell diameter and up (Table 16—III). They are usually equipped with roof-moving mechanisms (described later) to permit top charging. Door-charge furnaces and furnaces of special design, including units equipped with austenitic-steel bottoms to permit induction stirring, are also built.

Table 16—III. Heroult Furnace Sizes, Capacities, and Transformer Ratings.

Inside Shell Diameter	Usual Charge (Pounds)	Maximum Rated Charge (Pounds)	Usual Transformer Capacity (kva)
7'0"	6000	8000	1500/1800
8'0"	8000	10,000	2000/2500
9'0"	12,000	15,000	3000/4000
10'0"	16,000	20,000	4000/5000
11'0"	24,000	28,000	5000/6000
12'0"	30,000	35,000	6000/7500
13'6"	40,000	50,000	7500/10,000
15'0"	70,000	80,000	10,000/12,000
17'0"	100,000	120,000	12,000/15,000
18'0"	120,000	150,000	15,000/17,500
19'0"	150,000	180,000	17,500/20,000
20'0"	170,000	200,000	20,000/25,000
22'0"	240,000	280,000	25,000/30,000
24'6"	360,000	400,000	30,000/35,000

FIG. 16—3. Schematic cross-section of a Heroult electric-arc furnace, indicating typical refractories employed in (left) an acid lining and (right) a basic lining. Although only two electrodes are shown in this section, furnaces of this type (which operate on three-phase current) have three electrodes. (Courtesy, Harbison-Walker Refractories Company.)

The Furnace Shell and Lining—The shell of the modern electric-arc furnace is usually cylindrical in shape. It can be either riveted or welded, and is braced with structural-steel sections. As the development of the electric-steelmaking process has required the design of larger, more complex, higher-powered furnaces, problems have arisen which affect design, operation and maintenance. The shell has become a source of increasing trouble due to warping, burning and rupture. The shell on most existing large furnaces is an integral part of the furnace structure. Damage to the shell can weaken the structure and cause misalignment of operating parts mounted on it.

There are two methods for overcoming this difficulty on large furnaces:

(1) Build the shell as a unit structurally separate from the rest of the furnace structure; that is, to require the shell only to retain the refractories and charge while the operating parts of the furnace are supported on an independent structure unaffected by shell distortion.

(2) Eliminate rigid connections between the steel plates of the shell and the supporting yokes and buckstays, at least above the hearth line, to allow these parts to expand and contract independently of each other.

The shell of a cylindrical furnace has a flat bottom which can be laid first with several layers of clay, magnesite, or silica brick as required (Figure 16-3). As the side wall is constructed, the brick is set back to provide ledges for the granular material that will, after sintering in place, form the working bottom or hearth. Modern practice utilizes a much smaller amount of granular material than formerly was employed, and, with this design, it is possible to recover a large proportion of the bottom refractories when relining becomes necessary. The brick is placed easily around the door jambs, arches and in the door lining, as both jambs and doors have flat surfaces. The roof is a simple flat dome, and the water-cooled skewback type of

roof ring eliminates the necessity for special skew-shaped brick.

CHARGING METHODS

Charging methods for electric-arc furnaces fall into two classes—**top charging** and **door charging**.

Top-Charged Furnaces—There are two designs for modern top-charged furnaces: the **swing type** and the **gantry lift**.

In the swing type (Figure 16-4), the roof and the supporting structure for the electrode masts are lifted and swung to one side by motor-driven or hydraulic equipment.

The gantry-lift type, shown in Figure 16-5, has the electrode masts and the roof-raising mechanism built into a gantry crane that travels on rails along the charging floor. When the furnace is to be charged, the electrodes are raised to clear the shell, the roof is lifted and moved by the crane to one side of the furnace.

For medium-sized and large furnaces, top charging has the advantage of speed, as the entire charge can be placed in the furnace by drop-bottom buckets in a short time (Figure 16-5). In addition, very large pieces of scrap can be charged without being cut into charging-box sizes. However, scrap dropping from a considerable height results in a shock to the furnace bottom. To avoid this, a cushion of light scrap should be placed on the bottom by a magnet and this cushion used to absorb the shock.

Until recently, top-charge units of larger size were not extensively used. With heavy scrap, standard open-hearth machine charging offered and still offers an excellent method of placing the charge. However, within the last few years, the availability of heavy melting scrap has decreased, with considerable quantities of light scrap available. In utilizing top-charge furnaces, the furnace may be filled completely with light scrap which can be melted quickly by the use of transformers that can supply power at high rates to the furnace.

FIG. 16-4. A very large, modern Heroult electric-arc steelmaking furnace, with swing-type roof moved aside to permit top charging of the furnace by bucket. The rear electrode is partially hidden by the left front electrode.

FIG. 16-5. Drop-bottom charging bucket in position over the open shell of a gantry-type Heroult electric-arc steelmaking furnace.

Therefore, most of the new large furnaces being installed are top-charge units, with many old machine-charged units being converted to top charging. It is desirable with any large top-charge furnace installation to have open-hearth type of charging-machine facilities available for handling some heavy scrap and for making other additions.

Door-Charged Furnaces—Hand charging through the door is frequently utilized for very small furnaces, and, on somewhat larger units, charging with a chute is the method used. If larger furnaces are to be charged through the rear door, a charging machine is required. The standard open-hearth charging machine (described in Chapter 15) is most frequently employed.

Auxiliary Equipment—If the plant is designed for the use of hot metal, a 75 to 100-ton, four-girder, two-trolley crane is required for handling the ladles. This can serve also as the utility crane for the charging floor. If the plant is not to use hot metal, one or two 25-ton cranes with 10-ton auxiliary hoists will be needed in the charging bay. If top-charge furnaces are utilized, cranes in the charging bay should have ample capacity for han-

dling loaded charging buckets of whatever size is necessary.

Another item requiring space on the charging floor is equipment for drying any additions to the charge. This is necessary to prevent explosions in the furnace, with resultant blowing out of slag and damage to the furnace. It is also important that the moisture, both free and combined, be eliminated in order to reduce the possibility of absorption of hydrogen by the steel. The degree of dryness varies considerably in different shops due to the methods used. Some shops run a gas pipe into a pile of material and hope to obtain results with a gas flame. Other shops use large, flat pans set on blooms and heated by gas jets under the pans. A better method is to have one or two ovens heated with gas to about 1000° F, and place the material in charging boxes in these ovens. This method, however, has two disadvantages:

1. It is difficult to obtain uniform drying with the bulk load in the box, and
2. It requires a considerable amount of space on the charging floor.

The best method for drying is a small rotary kiln which does give uniform drying and does not require a large floor area.

Proper ventilation of the charging floor is of considerable importance. A recent development has been a furnace hood. This operates on the basic theory of dust control—confining the smoke and fumes at the source before they can disperse to adjacent working areas, and exhausting them through a duct to a point of collection and disposal. The specially designed, circular hood is attached to the furnace roof ring and permits operation and maintenance of the furnace without interference.

Pouring Facilities—The foregoing remarks have concerned the charging side of the furnace building. The pouring side has similar problems in track layout, cranes, and drying.

Since a large portion of the product will be alloy steel, and therefore, hot-topped ingots will be produced, provision must be made for preparing the molds. If it is to be done in the furnace building, track and floor space must be provided for preparing the molds for at least two heats. Since this requires considerable space, it is better for the work to be done in an adjacent building as, in addition to the floor space required, preparing the molds may interfere with crane service needed for other operations. If mold preparation is done on the pouring floor in a shop with a 200,000-ton annual capacity for steel making, a 25-ton crane is required in addition to two ladle cranes.

Cranes are rated in net tons of 2000 pounds and it should be noted that the capacities are based on the load on the hooks in accordance with the Association of Iron & Steel Engineers standard specifications, which make the load on the hooks the capacity rating. Previous to this time the weight carried by the drums was often used; and the weight of the cables, load beam, and hooks had to be subtracted to get the useful lifting capacity. It is the total ladle weight lifted and not the weight of hot metal that determines lifting capacity. The ladle, with its refractory lining, may be 40 per cent of the total weight, so that for 60 tons of liquid steel, a 100-ton crane is required.

After the heat has been poured into the molds, time must be allowed for the outer portions of the ingot to solidify and form a shell of adequate thickness or, in some cases, for the ingot to become completely solid before the mold can be removed by the stripping crane. On hot-topped molds, some plants provide a stationary stripper, located in the pouring aisle, to loosen the ingots. This device is installed on the floor with a base for holding one mold plus the ingot.

Ladle Drying and Preheating—Another requirement for the pouring floor is drying and preheating facilities for ladles, stoppers, and hot tops. When ladles are relined, the entire lining must be thoroughly dried and preheated, and after each heat the nozzle and replaced brick must be dried. This is necessary for three reasons:

- (a) To prevent explosions due to generation of steam.
- (b) To reduce thermal shock to the brick.
- (c) To reduce the chilling effect of the brick on the hot metal.

The usual method for drying ladles is to place a gas line with a crude burner in the ladle; this is fairly satisfactory for drying around a new nozzle.

Another method is to lay the ladle on its side, placing the open top against a brick wall and introducing the gas burner through a hole in the wall. This gives more uniform drying results.

Stopper Drying—The latest installations for drying the stopper-rod-assembly consist of a traveling-chain

conveyor passing through a gas-heated oven. The stopper rods are suspended vertically on this chain and pass slowly through the oven. The cycle is about 24 hours and when removed at the exit end, the stoppers and rods have been thoroughly and uniformly dried.

Hot-Top Drying—In most shops, hot tops are dried with heat from an open gas torch before they are placed on the molds. This is particularly true of the refractory-lined metal-encased type which are placed on metal stands for both preparation and drying between uses. It is presently proposed to completely mechanize the cleaning, coating, and drying of these tops through use of a conveyor line and suitable auxiliary equipment, all of which will result in more uniform preparation and fully-dried tops. The initial installation of such equipment has recently been completed in an open-hearth plant. At some plants, refractory hot tops may be dried separately in ovens where thorough drying at a uniform rate can be secured.

Electrodes—Sir Humphrey Davy, in his experimental work around 1800, used the current from a storage battery for the arc, and made his electrodes from wood, charcoal, and syrup of tar, molded under 100 pounds pressure.

In 1907, Dr. Heroult imported electrodes from Sweden for use in this country, because the largest electrode made in the United States at that time was only 12 inches in diameter. Importation was both slow and expensive, so he built a plant to produce carbon electrodes up to 24 inches in diameter. This plant supplied the electrodes for the large Heroult electric-arc steelmaking furnaces installed in what is now the South Works of the United States Steel Corporation, in Chicago, Illinois.

To the steel maker, there are two kinds of electrodes. Graphite (artificial crystalline carbon) electrodes (made from petroleum coke) are required in large electric steel furnaces, particularly for the manufacture of high-alloy steels. Carbon (amorphous) electrodes are widely used in small steel furnaces and in submerged-arc furnaces for the manufacture of ferroalloys, aluminum, calcium carbide, phosphorus, et cetera. Both carbon and graphite electrodes are used in electric furnaces because of their infusibility, insolubility, chemical inertness, electrical conductivity, mechanical strength and resistance to thermal shock.

Carbon electrodes in turn can be divided into two types; one, made of calcined petroleum coke, is used in aluminum reduction; the other, based upon calcined low-ash anthracite coal, is suitable for the other uses listed. Carbon and graphite electrodes are chemically essentially the same, but differ widely in their purity and electrical and physical properties.

In manufacture, both carbon and graphite electrodes start with mixtures of raw materials properly proportioned with a suitable bonding material, such as hot pitch or tar, and extruded or molded while still hot into "green" shapes. These are cooled, packed in powdered petroleum coke in furnaces, and baked at the desired temperatures. Carbon products are usually gas-fired in kilns to approximately 2000° F. Graphite products undergo this same gas-firing, followed by repack in Acheson electric-resistance furnaces, where they are heated to temperatures above 4000° F. This second treatment in the electric-resistance furnace results in the formation of graphite (crystalline carbon) and, through volatilization, removes most of the impurities. Electrodes of both types, after the foregoing processes, are cleaned, then bored and tapped—usually on both ends.

As an electrode is consumed in operation, a threaded nipple is inserted in the top and a new electrode is

Table 16—IV. Comparison of Carbon (Amorphous) and Graphite Electrodes

Properties	Graphite Electrodes	Large Carbon Electrodes
Specific resistance (ohm-inches)	0.0004	0.0017
Specific resistance (ohm-cm.) ..	0.0010	0.0043
Weight (lb. per cu. ft.)	96	99
Apparent density (grams per c.c.)	1.52	1.57
Tensile strength (lb. per sq. in.):		
Lengthwise	500	200
Crosswise	350	150
"Practical" oxidation point	900° F	700° F
Ash	0.50%	7.0%
Size ranges:		
Diameter (inches)	1½-30	8-40
Length (inches)	24-84	60-110
Weight (pounds)	1.6-2,960	160-7,100

screwed down tightly on the exposed end of the nipple. When carbon nipples are used, a carbon paste is used to improve electrical contact. Present trends are toward utilization of graphite nipples for joining carbon as well as graphite electrodes. Carbon and graphite electrodes vary widely in physical shape, dimensions and properties. These must be selected carefully, depending upon intended usage. A general comparison of the two types is shown in Table 16—IV. Where a single value is given it may be taken as average for a variety of sizes and shapes.

Carbon electrodes cost less than one-half as much per pound as graphite electrodes. However, the field of application for the carbon electrodes is limited by their capacity for carrying electric current, one of 20-inch diameter being rated at 17,000 amperes, while the 20-inch graphite electrode is rated at 34,600 amperes. For this reason, carbon electrodes seldom are used in furnaces with transformer capacities above 3000 kva. Figure 16—6 shows the relation between the current-carrying capacities of carbon and graphite electrodes.

FIG. 16-6. Relationships between current-carrying capacities of graphite and carbon electrodes of different diameters, as used in modern electric-arc furnaces.

When installed on the furnace, the electrodes pass through circular openings in the roof, spaced at the corners of an equilateral triangle (see Figure 16—7). Water-cooled rings are placed over these openings and

around the electrodes to act as a seal. The electrodes are supported by water-cooled clamps at the ends of the horizontal arms that extend over the furnace from vertical standards or masts. These clamps form the electrical connection between the power supply and the electrodes, and their design is a very important detail of furnace construction. Electrode holders of the wedge type have been used for some time but now are being supplanted by so-called automatic electrode holders, usually of the spring-clamp air-release type which can be operated from furnace-platform level to adjust the electrodes (Figure 16—7).

On a typical arc furnace, the secondary leads extend in the form of bars through the transformer case. From this point, the shortest possible delta connection is made with heavy copper terminals placed generally in the transformer vault wall. The necessary secondary cables are utilized and placed in the form of a hollow rectangle to eliminate skin effect and give maximum conductivity. These cables connect to terminals on water-cooled bus tubes mounted on non-magnetic castings, remote from steel parts so as to minimize hysteresis and eddy current losses. The electrode arms, with horizontal section insulated at the rear, carry the bus tubes and electrode holders. The arms are usually in the form of an inverted-L cantilever mast. Each mast is capable of being raised or lowered independently to provide separate movement of any electrode.

The raising and lowering of the electrodes is accomplished through wire cables with motor-driven gears and winch units. It is the control of the motors driving these units that governs the successful operation of the furnace during the melting period.

Soderberg Electrodes—This is a continuous type of electrode made of a special paste that is baked by the heat of the furnace. A thin-steel cylindrical casing supported by two pieces of strip steel welded to the casing, one on either side, is filled with this paste. As the casing is lowered into the furnace, a new section of casing is welded to the top of the last section. As the bottom of the electrode is consumed in the furnace, the supporting strips are lowered and the electrodes slipped through the clamps. The heat of the conducting current plus the heat of the furnace bakes the paste on its downward travel.

This type of electrode has been built in sizes up to 27 inches by 66 inches, with a conducting capacity of 80,000 amperes. It is used on reduction furnaces where rapid movements of the electrodes are not required. Its application to arc furnaces, however, is doubtful because of the complicated design of the supporting structure plus the mechanism for quickly raising or lowering the electrodes for control of power during the melting operation.

The Power Transformer—Transformers for electric-arc furnaces are similar in design to large power transformers, except that they are designed for both delta (Δ) and wye (Y) connections on the primary side with several full-capacity taps. Because of widely fluctuating load, which at times approaches short-circuit conditions, special bracing of the windings and extra insulation between turns is required. This latter is needed to withstand the high-voltage surges set up by switching operations. In normal practice, there may be 125 switching operations per 24 hours, and the resulting surges often equal five times normal voltage. These transformers are designed to suit the furnace, and their specifications usually are written by the furnace manufacturer.

All transformers are rated in *kva capacity*. As discussed in Section 13 of Part 3 of Chapter 2, the char-

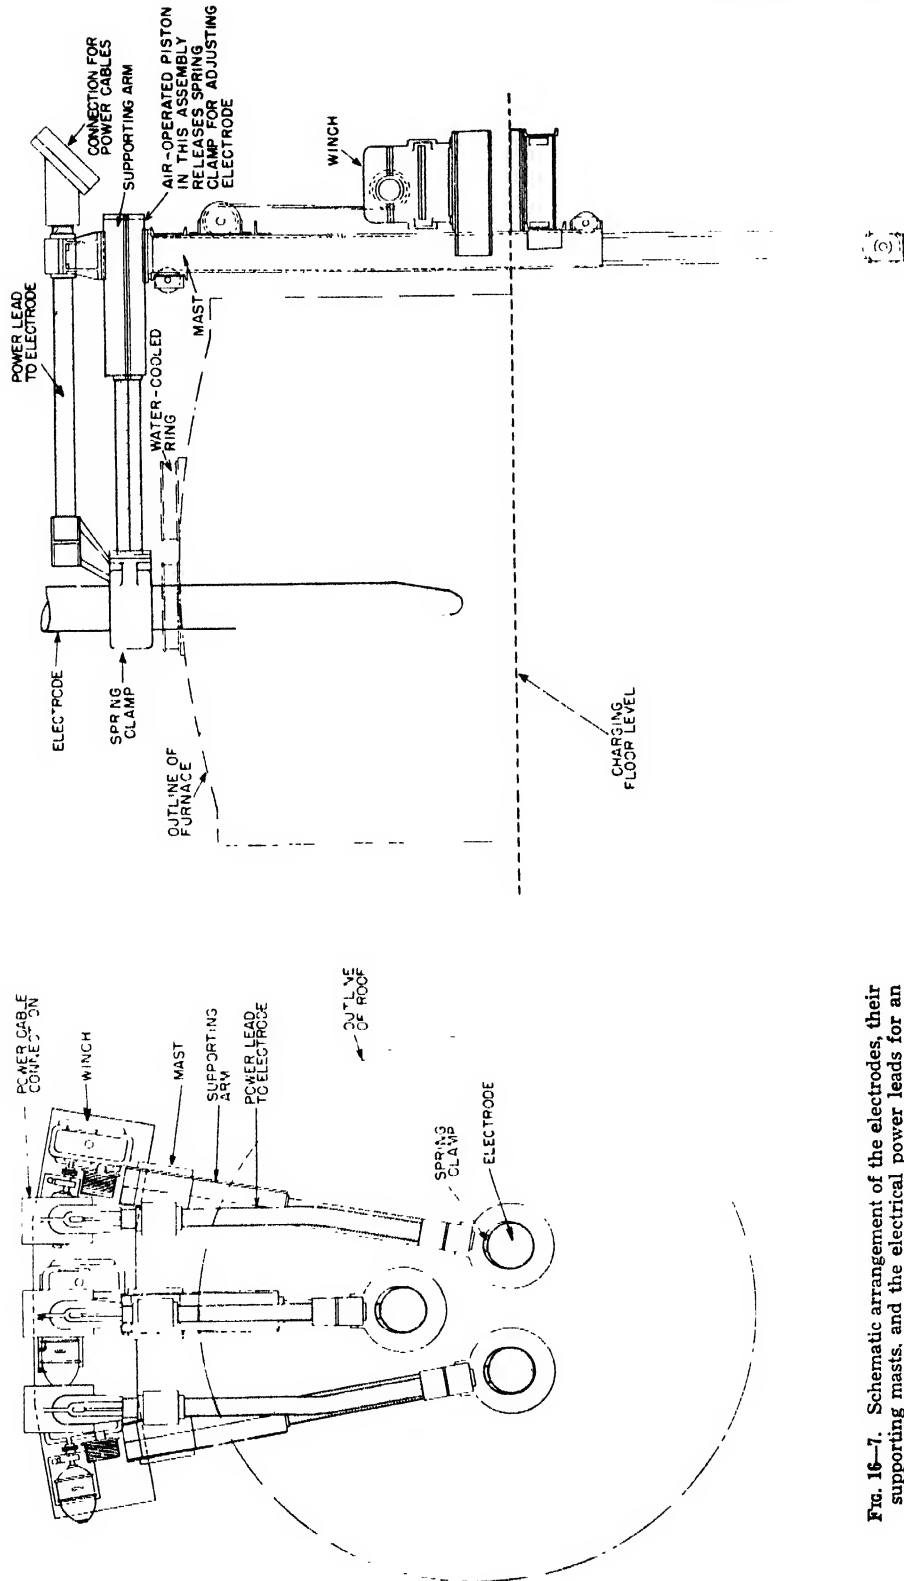

FIG. 16-7. Schematic arrangement of the electrodes, their supporting masts, and the electrical power leads for an electric-arc steelmaking furnace.

FIG. 16—8. Diagram depicting the volt-ampere characteristics of an arc with respect to its stabilizing element.

acteristics of an alternating-current circuit may result in the voltage and current being out of phase. This results in a loss of power, and the ratio of the useful power in the circuit to the apparent power supplied to it is called the power factor. The unit "kva," an abbreviation of "kilovolt-amperes," represents the product of the impressed voltage and the current in the circuit, and is a measure of the apparent power.

$$\text{kva} = \text{kilovolts} \times \text{amperes}$$

The useful power in the circuit is measured in kilowatts.

$$\text{kilowatts} = \text{kilovolts} \times \text{amperes} \times \text{power factor}$$

Kilowatts are equal to kva in the unusual case when the power factor is 1.0. The power factor is usually less than 1.0, so that the useful power (kilowatts) is usually less than the apparent power (kva).

Tap Changers—During the melt-down period in an electric-arc furnace, the delta connection on the primary winding is used as this gives higher secondary voltages. Each winding of the three-phase transformer has from four to six taps, which are terminated in a motor-driven tap changer located in a separate tank or control cubicle mounted on the side of the transformer. By changing from delta to wye connection, the voltages on the taps give secondary voltages in the proportion of 1.0 to 0.58. The mechanism of the tap changer is inter-locked with the main circuit breaker so that it is impossible to change taps under load.

Reactors—Due to the fact that, when starting to melt a heat, the resistance of the secondary circuit is very low, means must be provided to limit the current flow. This is done by adding reactance in the primary circuit. On small 60-cycle transformers (2,000 kva) the value of this external reactance may be 0.012 ohms, which value decreases to about 0.003 ohms on the 12,000-kva, 60-cycle size. On 60-cycle systems, sufficient reactance is obtained as inherent transformer reactance and reactance of leads to eliminate the use of any external reactance on transformers in excess of 7500-kva capac-

ity. On 25-cycle power supply, the limiting value is approximately 15,000 kva.

Where large transformers are used, it is important to maintain the total of the impedance of the circuit to a minimum, and secondary voltages of sufficient value must be utilized to permit introduction of the power at a desirable power factor.

Size of Transformers—The size of furnace transformer required is governed by several factors.

- (1) Whether hot metal or a 100 per cent cold charge is to be used.
- (2) Restrictions that may be imposed by the power supply.
- (3) The capability of the electrodes to carry the heating current and the ability of the charge to absorb it.

The rate at which a given charge will absorb heat is measured by the temperature gradient within the mass. This rate declines continuously as the average temperature of the charge rises and reaches zero at temperature equilibrium in the furnace chamber.

On arc furnaces up to and including 3000-kva capacity, voltage taps generally range from 250 volts, phase to phase, with transformer primary connected delta, down to approximately 90 volts with transformer primary connected wye. On larger furnaces with transformers of 20,000 kva and greater, secondary voltage taps may range from 550 volts with primary connected delta, down to 150 volts with primary connected wye.

The Secondary Circuit—An electric arc converts large quantities of electric power into heat in a space of small volume. This concentration of heat developed at a high temperature—about 6300° F (3500° C) for the carbon arc—is the initial consideration in the design of the furnace chamber. A peculiar electrical feature of the arc is that its voltage decreases with an increasing current as shown in Curve A (Figure 16-8). Hence, the arc is inherently unstable.

The condition for stability of an electric circuit with

a constant voltage is a positive volt-ampere characteristic, that is, an increase in voltage drop in the circuit simultaneous with an increase in current. To obtain this stability, something has to be added to the secondary circuit that will produce a positive volt-ampere characteristic and this something is reactance. Curve B (Figure 16—8) shows the curve for this part of the secondary circuit, and since this reactance is in series with the arc circuit, the two curves combine and form the total curve C. The dotted line a-a shows the lower limit of stability, and stable arc conditions are obtained by adjusting the length of the arc for some amount of current higher than the critical value indicated by the line a-a. In general, the circuit is stable with about 50 per cent reactance-volts drop in the arc circuit. This does not cause an energy loss, but does lower the power factor to about 87 per cent.

The arc-furnace circuit, when operated at a constant given voltage, supplies a constant power factor load during the phase of operations when that selected voltage is used. However, the reactance of the secondary circuit is what determines the value of the power factor.

The secondary circuit thus consists of a fixed reactance of supply lines, cable, transformers, bus and furnace leads, and a variable resistance consisting of the fixed resistance of these same circuit elements plus the variable resistance of the arc itself. The voltage applied to the circuit may be varied by adjustment of the transformer taps. The power at any given voltage is varied by changing the resistance of the arc. This may be done by raising or lowering the electrodes; this is accomplished by an automatic control that seeks, by positioning the electrodes, to find and maintain constantly the current value that has been selected by the furnace operator.

If the kilowatt and the kilovolt-ampere inputs are plotted for any given voltage with variations in the current input, the curves will be similar to those shown

on Figure 16—9. As the current increases, the kilovolt-ampere input increases in a straight line, since it is the product of kilovolts and amperes. The kilowatt input, however, increases only until a current is reached that will produce a power factor of 0.707 in the circuit. Further increases in current beyond this point cause a decrease in kilowatt input with increased kilovolt-ampere input and lower power factor.

Since a part of the energy input is dissipated in I²R (heat) losses in the transformer bus and leads, the actual kilowatt input to the furnace itself will be less than that shown on curve A (Figure 16—9) and will follow curve B, reaching a maximum at some circuit power factor higher than 0.707, depending upon the resistance of the other circuit elements. Since the losses to these other elements of the circuit vary as the square of the current, the result is a falling efficiency curve as shown (Figure 16—9).

It is perhaps unfortunate that current provides the most convenient factor for automatic control of the circuit. Furnace operators may thus be misled into associating heat input with amperes rather than kilowatts, and in their attempts to get high heat input into a furnace, use current settings beyond those that give the optimum kilowatt input, as defined above. Such practice results not only in high kilovolt-ampere demand and lower power factor, but also in the actual loss of steel production and increased incidental costs.

It is the custom in modern shops to determine this maximum current for each voltage setting and give this information to the melter. The following table has been worked out for a three-phase, 10,000-kva furnace transformer:

Volts	200	250	300
Optimum current (amperes)...	12,910	16,130	19,300
Maximum power (kw.)	3000	4700	6765
Approximate power factor (per cent)	74	74	74

FIG. 16—9. Curves illustrating electrical characteristics of the electric arc-furnace circuit.

The Primary Power Supply with Circuit Breaker—

The type and size of circuit breaker to use for the primary circuit on large furnace transformers is a matter of controversy. Since the power supply is usually a high-capacity utility system, the required rupturing capacity of the breaker is often 1,000,000 kva. In actual operation, the breaker is opened each time a transformer tap is changed. There may be 100 such operations per day, and these high-rupturing-capacity breakers are not designed mechanically for such service. In addition, this type of breaker is designed primarily to interrupt heavy currents. Its operation is partially dependent on the magnetic field created by these heavy currents to quench the arc. When operating with only the magnetizing current of the transformer to break, this effect is not present and there is a tendency to burn the contacts. As a result of these factors, it is necessary to make both mechanical and electrical repairs to the breakers with each furnace relining.

There are several methods used to minimize circuit-breaker maintenance:

- (1) During the melt-down period there is in effect a series of short circuits on the transformer secondary circuit. If a breaker with a capacity to open the most severe of these short circuits is selected, the 1,000,000-kva rupturing-capacity size is not required, and a breaker with a lighter operating mechanism can be installed and the maintenance reduced. This breaker, however, must be inter-locked so that it will not function if there is a short circuit or ground within the transformer, and a back-up breaker must be in-

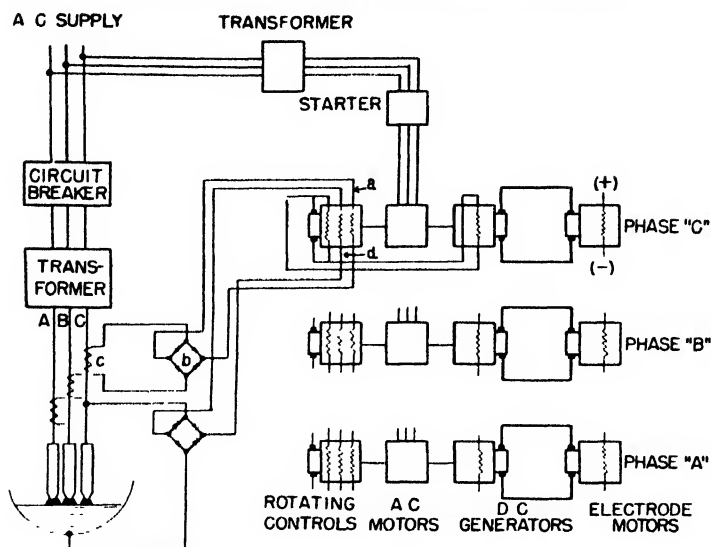

FIG. 16—10. Schematic elementary diagram of one type of regulating system for electric-arc furnaces. (Courtesy, Westinghouse Electric Corporation.)

stalled ahead of the furnace-shop power supply, set to operate under these conditions.

- (2) Compressed-air-operated breakers can be used for this work. The air required for their operation is supplied from a small compressor. This breaker has light moving parts and is designed for frequent operation. It has been very successful on installations up to 22 kilovolts and can be specified for the full rupturing capacity required by the power system.
- (3) Another type of switch is an air-operated disconnecting unit with sufficient interrupting capacity to open under electrode short circuits. A back-up breaker is required with this type of switch.

Control of Power Supply to the Charge—The early arc-furnace regulator was a simple current-operated device. The current transformers in each phase of the secondary circuits had secondaries which were connected to the regulating coils, and the pull of this current in the coil was balanced against a spring. Contacts on the plunger made connections with either the up or down set of contacts when the electrode current was higher or lower than the current setting. These contacts were relayed to the control of the electrode motors and caused them to operate in the proper direction as the current varied from some pre-determined value.

This control was unsatisfactory because the restraining force of the spring was constant. The variations of current during melt down are rapid, and the mechanical movement of the electrodes comparatively slow, so that this control responded to the average value of current variation. Furthermore, a three-phase system of currents in an electric furnace is very complex and the values of the currents in the regulator are interdependent, the value in any phase at a given time being determined by conditions in the other two phases, as well as by the length of the arc in that particular phase.

It is well known that the voltage drop across the arc will increase as the current decreases, and vice versa. Hence, if the varying pull of a coil or other regulating device, which is proportional to the current in the electrode, is matched against a restraining force that is pro-

portional to the voltage drop across the arc, the utmost sensitivity to changes in arc length can be obtained in the regulator.

The above is the principle used for the constant-potential, magnetic control systems used on most arc furnaces and, when combined with dynamic braking on the electrode-motor circuit, has been the standard method of control. This is known as the balanced-beam control.

Quite independently of the arc-furnace industry, new methods of regulation using rotating equipment with variable-voltage control were developed. When applied to electrode control, the several systems based on this principle balance currents in the electrode circuits against the voltage across the arcs and combines these with variable-voltage controls on the electrode motors.

The advantages claimed for these methods are as follows:

1. Variable-voltage control of the electrode motors results in motor torques directly proportional to the average unbalance between the current in the electrode and voltage across the arc, and gives an increased speed of response to these motors, resulting in smooth acceleration and deceleration.
2. When maximum unbalance occurs, the maximum permissible voltage can be applied to the motors causing high-speed withdrawal of the electrodes.

Figure 16—10 shows an elementary wiring diagram of one of these systems. The current-control field of the regulating element (a) is energized by a dry-type rectifier (b) which in turn is connected to a current transformer (c) in the electrode circuit. The potential-control field (d) is energized in a similar manner from the voltage drop between the electrode and the shell of the furnace.

When the breaker is closed, voltage is applied to the potential control field which causes the generator voltage to build up in the direction to lower the electrodes. When the first electrode strikes the metal charge, the voltage drops to zero causing the electrode motor to stop. When a second electrode strikes the metal, a current will flow causing the current-control field to become energized, which

acts to raise the electrode and establish an arc. As the arc is lengthened, its voltage increases and the current decreases until a balance is established between the potential and current-control fields.

Provision is made for manually controlling the electrodes individually, or automatically in a group. The operator sets the voltage tap on the furnace transformer and adjusts current input by a rheostat to the value desired.

3. Installations with this type of control, having smaller load fluctuations because of the increased speed of response, decrease electrode breakage and result in a decrease of kwh.-consumption per ton of ingots.
4. It is possible to build this control with the three generators driven by a single motor with a small flywheel, assembled on a common bed plate. Should the alternating-current power fail, there is enough momentum in the flywheel to keep the set spinning, and maintain voltage in the direct-current generators for a sufficient time to raise the electrodes out of the bath.

Operator's Control Panel—With each electric-arc furnace, it is customary to mount a control panel, usually in the wall of the transformer vault, with the instrument side of the panel flush with the outside wall. This panel contains all the instruments, rheostats and control switches for the operation of the furnace, with the exception of the control for the tilting mechanism. This master control station usually is located near the charging side of the furnace.

One of the control switches, with a red and a green indicating lamp on either side, closes and opens the main circuit breaker. Another operates the tap changer, but is so interlocked that it cannot be operated unless the main circuit breaker is open. If rotating-type control is used, the starting switch for the set, plus three switches to manually control each electrode motor, are needed.

There are three ammeters, one for each phase, and above each a rheostat. The value of the current that is to be maintained in each phase by the automatic control is set by the individual rheostats.

Above the ammeters is a wattmeter and a power-factor meter, which indicate the useful power being taken into the furnace and the power factor. There is some question of the accuracy of the power-factor reading, because of the complexity of the varying currents in all three phases, but it is a guide point and is required on all boards.

An integrating watthour meter, which adds up the kilowatt hours on the furnace, completes the normal complement of meters. Some operators install a graphic watthour meter to keep a record of the power changes and consumption at various times during the heat.

Power Requirements—Power requirements for actual melting are variable and depend upon the definition of when the charge is melted. Generally, it is assumed that the charge is melted when no further scrap remains and the metal has reached a temperature of 2850° F. Depending upon thickness of the lining and other variables that affect furnace efficiency, the kilowatt-hours required for actual melting vary from between 400 and 425 per ton.

The problem of determining the amount of power to be used during the meltdown period has to be based on several factors incident to the furnace installation and type of charge, but the maximum useful power that can be used is determined by the characteristics of the secondary circuit.

The arc itself is virtually a resistance drop, which is in series with a large reactance drop caused by the leads and transformer winding. The resistance drop is in phase with the secondary current, while the reactance drop is 90 degrees out of phase. The resultant relation is the vector sum of these two drops, and the cosine of the angle between the resultant current and the voltage is called the power factor. The useful power or kilowatts used to melt equals the product of the voltage drop times the resulting current times the power factor. When the ampere loading reaches a point where the power factor is 0.707, maximum power is going into the charge. This power factor (0.707) is that of the secondary circuit. Since the current and potential transformers that operate the power-factor meter are installed on the primary circuit of the power transformer, there is an additional reactive drop in these windings; so that maximum ampere input to the furnace occurs at from 0.75 to 0.80 power factor as read on the meter.

The maximum useful amperes for a given secondary voltage can be found by increasing the current until the kilowatt-meter reading reaches a maximum and then gives decreasing readings. The amperes at this value are the maximum to use, as any further increase not only will reduce the melting power but also heat up the leads and the transformer.

Following the meltdown period, the power requirements are reduced while the heat is worked and refined. This period depends on the composition of the steel, quality of scrap, furnace condition, and shop practice.

The rapidity of melting is a function of the amount of energy introduced in a given time. Theoretically, there is no limit to the amount of power that can be introduced to the furnace. However, if the energy introduced to the furnace is not absorbed by the charge, high gradient temperatures occur which will cause deterioration of the side walls and the roof. Thus, rapidity of melting depends entirely upon how rapidly energy can be introduced to the charge. As the energy introduced is largely in the form of radiation, it follows that light scrap with greater surface area can usually be melted more rapidly than heavy scrap. It is important, therefore, that the rate of power input does not exceed that rate of heat absorption by the charge. It is always advisable to utilize the minimum secondary voltage necessary to introduce the required amount of power at the proper power factor. On this basis, the arc length is at a minimum and damage to refractories is lessened.

Some melters start a meltdown with a lower voltage and amperage than they use after the melt has started. In a published record of a 50-ton furnace having the following transformer taps: 282, 242, 220, 199, 165 and 115 volts, good furnace results were obtained with these values:

	Volts	Amperes	Minutes
Start	199	25,000	15
	282	32,000	130
	242	25,000	15

In a shop using a 90,000-pound charge of alloy steel, the average kwh. per heat was 24,600 or 547 kwh. per ton for 200 heats. If 450 kwh. per ton were required for melting, then 97 were required for refining. The average time from tap to tap was 6 hours, 8 minutes, of which 37 minutes were required for charging. The average input during the meltdown period was 12,300 kva.

In connection with power input, the maximum input to the furnace is measured by two factors:

1. The rate at which a given charge will absorb the heat is a function of the temperature gradient

within the mass. This rate declines continuously as the average temperature of the charge rises and reaches zero at temperature equilibrium in the furnace chamber.

Inasmuch as the energy developed at the arc is largely radiant energy, the rate of heat absorption by the charge is largely dependent upon the area exposed to the radiation; hence, with large pieces of heavy scrap, the rate of heat absorption is considerably less than that which is afforded by the use of very light scrap with large area.

2. On small furnaces, the electrical circuit, including the reactor, is adjusted so as to give an average primary power factor during meltdown of approximately 87 per cent at full load. There are cases, however, where the companies supplying power object to the maximum swings in demand and insist on additional reactance in the primary circuit to

dampen these swings and reduce the power factor to 80 per cent or 82 per cent.

In Figure 16—9, the curve of power input plotted against current indicates that a relatively wide variation in current can occur without an appreciable change in useful power input. Thus, very little is gained in power input if a furnace is operated with a secondary power factor of less than 75 per cent. This means that the power factor measured on the primary side of the furnace transformer would normally be close to 80 per cent.

As a rule of thumb, it can be said that it is not economical to operate an arc furnace with a primary-side power factor under 80 per cent. It should be noted that the 0.707 power factor mentioned earlier as providing maximum power input to the charge is measured on the secondary side of the transformer.

SECTION 3

THE BASIC ELECTRIC-ARC FURNACE PROCESS

Before the location for an electric-furnace plant for the production of ingots by the basic process can be selected, its capacity and probable growth must be known, as an ample electric-power supply must be available. If it is assumed that the plant will have an initial annual capacity of 200,000 tons of ingots per year and a future capacity of 400,000 tons per year, a power supply of 50,000 to 60,000 kilowatts must be available.

This amount of power is not available in the generating stations of the steel plant and due to the highly fluctuating loads, poor power factor and load factor, it is not desirable on some utility systems. For these reasons, a source of power must be found before deciding on a plant location.

Installations have been made as additions to existing open-hearth shops. These involved low investment charges, as the electric furnace was installed either on the location of a dismantled open hearth or in an addition to the building. Hence, existing cranes, stock facilities, utilities, etc., could be used for the new installation.

Some of the objections to this type of layout are:

- (1) The chance of carbon pick up from the hot metal mixer (from flakes of graphite or kish floating in the air).
- (2) Difficulties in scrap segregation.
- (3) Congestion on the pouring floor.

Several plants were installed as complete steelmaking units which required a full complement of buildings, cranes and tracks. This arrangement is more costly but allows for segregation of materials, setting up a working force who are concerned only with making electric-furnace steels, and supervision is concentrated on the products.

Stocking and Charging Facilities—A most modern design for a basic-process electric-furnace plant calls for a lower level stockhouse located as an extension to the end of the furnace building or adjacent and parallel to the furnace building. At either of these two locations, drop-bottom charging buckets, ranging in capacity from 100 to 3300 cubic feet as required by furnace size, are loaded at ground level and subsequently moved by an overhead crane in the first instance or by transfer car and overhead crane in the second instance to the furnace floor, from which point they may be charged into the furnaces. Some older plants originally equipped with door-charged electric furnaces have two-level

stockhouses, the higher level being for the charging cars which can be loaded on the furnace level and the lower level used for storage bins.

In electric-furnace practice, the different lots of alloy scrap are kept in separate bins and, during normal times, between twenty and forty bins are required. When the use of virgin alloys is restricted, scrap must be segregated further and perhaps 65 or more kinds of scrap must be used, depending upon the grade of steel being made, as discussed later under "Utilization of Steel Scrap." Few stockhouses are designed for this practice and this may result in stocking out of doors.

Since the charge should be dry before it is placed in the furnace, a covered stockyard is advantageous. For a 200,000-ton plant, at least two 10-ton cranes equipped with lifting magnets are required in the stock yard. In those plants where the boxes are loaded on the lower level, they are placed on platens which are raised to the charging cars on the furnace floor. A 30-ton crane is required for this service. This layout calls for the loaded boxes to be carried to the scales and weighed before placing on the platen, which holds three or four boxes. This system has the advantage of easy, accurate weighing and conserves space in the stockyard. With this system of stocking, a study of crane movements with timing cycles is required as the operation can be bottlenecked by the cranes.

Tracks for both the incoming supplies and the charging cars are important factors in the plant layout. The daily supply of scrap for a 200,000-ton annual capacity shop will require a minimum of 11 railroad cars, in addition to those required for limestone, ore, brick, etc. In addition, storage tracks, located nearby, are required for these materials to provide for possible irregularity of railroad movements.

UTILIZATION OF STEEL SCRAP

Scrap Segregation—The necessity for conserving the valuable alloy content of steel scrap, to economize in the use of virgin alloys and to insure that only the elements desired are introduced in making the steel, makes it absolutely necessary to segregate or separate the available scrap into stock piles of identified grades. When the "product mix" (grades of steel produced) varies a great deal, the scrap classification by alloy content must be much more extensive than for a specialty plant producing the same grade continuously. One plant, making

various grades of steel by the basic process, including alloy and stainless steels, has found it necessary to segregate their scrap stock into 65 classifications.

The scrap stock may be revert or home scrap from the rolling mills and forge shops of the same plant where the electric furnace operates; it may be obtained from scrap dealers, from customers, from other steel producers, or from sister plants. To produce economically the wide range of steels common to modern practice requires careful selection of the scrap, and a scrap segregation and control plan is essential.

The term "segregation" as used here may be defined as the separation of a mass of mixed scrap into piles of individual compositions. Close adherence to a definite scrap-segregation program is essential if the greatest benefits are to be obtained with respect to alloy conservation and melting close to the desired composition. Consistent melting practice is an aid in maintaining mill schedules for the production and delivery of steel, and helps to obtain optimum tonnage from a given unit as well as to maintain steel quality at the high standards demanded by industry. Any even temporary disregard of the scrap-segregation program will lead to loss of alloys, and non-oxidizable elements such as nickel and copper may enter and remain in the bath and cause the heat to be scrapped or, at best, diverted to another order which originally did not require the use of so many valuable elements. For example, chromium can be oxidized from a heat ordered as nickel-molybdenum steel but it is a costly and wasteful process. On the other hand, nickel cannot be oxidized from a chromium-molybdenum heat; therefore, if it is present and the order restricts the nickel content to no nickel or very low limits, the heat must be diverted or scrapped.

Methods for Insuring Proper Segregation of Scrap—The segregation of home scrap is comparatively easy but the introduction of outside or foreign scrap imposes a problem. Several methods are available for testing the scrap to determine if it is what it is supposed to be. These include chemical analyses of selected samples, spectrographic analysis, and less costly and less accurate methods such as magnetic tests, to separate magnetic from non-magnetic scrap, and the "spark" test. The latter is made by holding a piece of scrap against a grinding wheel and observing the shower of sparks; it is possible for a trained observer to differentiate between the various kinds of steel scrap by noting the color of the spark, the length of the spark lines, and the characteristics of the ends of these lines. In addition, a couple of rough tests may be mentioned; for example, "spot tests" which permit rough estimates to be made of the amount of nickel or one of several other elements present by the use of a chemical solution or solutions applied to a clean surface of the sample to be tested. Another rough test is the "pellet" test by which a few elements may be detected by viewing oxidized particles from "spark" tests under a magnifying glass.

Physical Requirements of Scrap—The size of the scrap or its bulk density is of importance. The size may vary from ingots of various sizes to turnings from machine shops. Heavy scrap (ingots, ingot butts, crop ends) has considerable weight per unit volume, while the weight per unit volume for light scrap is low. Therefore, if there is too much light scrap in the charge for a given heat, the total volume of heavy and light scrap will exceed the volume of the furnace and part of the scrap cannot be charged until a portion of the charge is melted down. A charge made up entirely of heavy scrap is also objectionable, because it does not permit the shielding of roof and walls during the melt-down period to the same extent as a mixed charge of greater volume, and

results in decrease of refractory life. Another physical requirement, especially with heavy scrap, is that the pieces are not too long, so that the charge in the furnace may be kept relatively dense and not opened up by longer pieces which, as a rule, do not lie in a horizontal plane. If the scrap charge is made up of approximately 40 per cent heavy, 40 per cent medium, and 20 per cent light scrap, a density usually is obtained which reduces the number of "back charges" (the charging of additional scrap after the original scrap charge has melted down).

Selection of the Scrap Charge—With an efficient scrap-segregation plan in effect and with scrap available that has the proper physical characteristics, the charge should be made up as follows:

1. Grades of scrap must be selected which together contain the elements necessary to make the heat ordered. The charge may contain all or part of the specified elements, with care being taken to see that no scrap is included that contains elements which are not a part of the specification. This is imperative if the scrap contains an element which cannot be oxidized by regular practice.

2. For economical operation, each element contained in the scrap selected should approach by weight, as closely as possible, the number of pounds of that element required to meet the lower range of the chemical specifications (for that element) in the ordered heat.

3. Knowing the amount of the various elements contained in the combination of scrap selected for a heat, the total amount of virgin alloys necessary to make the heat are calculated. This calculation is based on the weight of the heat to be made (furnace capacity and amount specified by an order) and the specification. In making these calculations, allowance must be made for adjustments during the making of the heat; for example, losses in melting some alloys and the possible absorption of certain alloying elements from the bottom and banks of the furnace. In regular practice, a heat made to a low alloy specification occasionally finishes outside of the specified composition ranges when the heat is made immediately following a high alloy specification, such as a stainless grade of high-manganese steel, etc. The usual practice to overcome this difficulty is to make a so-called wash heat; i.e., a heat of medium alloy specifications, but containing the same elements, made following the high-alloy grades. The purpose of the "wash heats" is to have any absorption of elements from the furnace bottom and banks take place in a heat in which the increase in certain elements is not harmful and thus prevent high residuals in the low-alloy heats which will follow.

4. Efficient operation makes it necessary that the scrap selected for a given charge is not only satisfactory for that charge but that it be selected on the basis of the scrap available for efficient operation over a period of time. If only heavy or medium scrap were used for a few heats, it is probable that these particular heats would be speeded up. If, however, at the same time a large inventory of light scrap (turnings, punchings, etc.) were accumulating, excessive amounts of this light scrap would have to be charged in later heats, probably with back-charging, and the delays and damage to refractories would far off-set any gains in the few heats made with heavy and medium scrap.

5. It is probable that no part of the routine of charging the furnace is of more importance than the loading and weighing procedures. Unless the proper type of scrap is selected and correctly weighed, the final product probably will be of the wrong composition, because

all adjustments are based on what is assumed to be the correct weight of the scrap charged originally.

CHARGING, MELTING AND FINISHING

Charging the Furnace—The various types of charging equipment have been described earlier in this chapter. Regardless of the type of furnace, whether door or top-charged by hand, chute, bucket, or charging machine, an effort should be made to place the charge as accurately as possible.

The power is turned off and the roof and electrodes are moved out of the way in the case of top-charged furnaces. With door-charged furnaces, the electrodes are raised as high as possible to prevent breakage during charging, and the charging started. Light or medium scrap is charged in a thin layer on the bottom or hearth, because this type of scrap melts faster than large pieces when the metal directly under the electrodes melts and drips down through the charge and collects on the bottom of the furnace. Heavy scrap is charged in the area within or adjacent to the triangle or "delta" formed by the electrodes and must be charged in such a way that it will not shift during melting down and cause possible breakage of electrodes by falling against them. After this, light or medium scrap is usually piled high around the sides of the furnace to protect the roof and side walls from the arc during the melt-down at high power input.

Ferro-alloys, alloying oxides and virgin alloys which are not easily oxidized, can be and usually are charged in the furnace prior to melting down.

It is desirable to melt down with excess carbon in the bath in order that some carbon may be worked out by ore additions. If the metallic charge is too low in carbon, a recarburizer in the form of coke or scrap electrodes is charged with the scrap to allow for a carbon content of the bath at melt-down that will be 0.15 to 0.25 per cent higher than the carbon content of the finished steel.

Ore is added to lower the carbon content. Various operators may charge the ore with the scrap, or when the charge is partially melted, or when the charge is completely melted. The control of the boiling action caused by the addition of ore, cinder and roll scale to eliminate the excess carbon is one of the most important factors in the production of high-quality steel. The methods of charging the ore may be adapted to meet the conditions existing with a particular charge to give the best results in making the specified grade of steel.

Any general description of making steel in the basic electric-arc furnace must be broad enough to include double- and single-slag methods with other variations.

Considering as the basis for discussion the double-slag, cold charge practice, because it is relatively the most complicated, it can be divided into: (1) the melt-down and/or oxidizing period, (2) the slag-off period, (3) the reducing period, and (4) the tapping period.

Melt-Down and/or Oxidizing Period—When charging has been completed, the bank in front of the charging door is built up with refractory material (dolomite) to form a breast or dam to keep the molten metal from slopping out the door (furnaces may have more than one door if the size warrants). The door (or doors) is closed and the electrodes are lowered to about an inch above the scrap. The main circuit breaker is closed, an intermediate voltage is selected with proper current setting on the rheostats, and the arcs are struck under automatic control. After approximately 15 minutes (to allow the electrodes to bore into the scrap), maximum

voltage and current should be applied for the fastest possible melting of the scrap. The initial slow start is to shield the lining and roof from the heat of the arc, which lengthens as the voltage is increased.

The melting period in the basic electric furnace is the most expensive period in its operation because power and electrode consumption are at the highest rate during this period.

The electrodes melt the portion of the charge directly underneath them, and continue to bore through the metallic charge, forming a pool of molten metal on the hearth. From the time the electrodes bore through the scrap and form the pool of molten metal on the hearth, the charge is melted from the bottom up by radiation from the pool, by heat from the arc, and by the resistance offered to the current by the scrap. This continues until the charge is entirely melted.

From the time molten metal begins to form until the entire charge is in solution, oxidation occurs in varying degrees. During this period phosphorus, silicon, manganese, carbon, etc., are oxidized, the reactions being somewhat as follows:

1. (a) $2 \text{Fe} \cdot \text{P} + 8 \text{FeO} = 3 \text{FeO} \cdot \text{P}_2\text{O}_5 + 11 \text{Fe}$
 (b) $3 \text{FeO} \cdot \text{P}_2\text{O}_5 + 3 \text{CaO} = 3 \text{CaO} \cdot \text{P}_2\text{O}_5 + 3 \text{FeO}$
2. $\text{Si} + 2 \text{FeO} = \text{SiO}_2 + 2 \text{Fe}$
3. $\text{Mn} + \text{FeO} = \text{MnO} + \text{Fe}$
4. $\text{C} + \text{FeO} = \text{CO} + \text{Fe}$

Oxygen for these, as well as other oxidizing reactions, is obtained from (1) the oxides on the original scrap surface, (2) free oxygen in the furnace atmosphere, (3) oxidation of the scrap during melting, (4) calcination of limestone (if used), (5) oxidizing action of the gases in the furnace, (6) oxides of alloying elements added in the furnace, (7) ore, cinder and scale (if charged or added later), and (8) oxygen gas introduced into the molten-steel bath through a pipe or lance. The direct use of oxygen gas (Item 8) is extremely important in modern practice from the standpoint of removing carbon from the bath rapidly.

Oxidation practice must be varied with different grades of steel. For example, low-carbon steels and those in which the hydrogen content must be low, require a relatively high degree of oxidation. As the oxidation progresses, the temperature of the bath is raised to promote carbon removal and to increase the fluidity of the bath to the point where inclusions may rise through the molten metal to its surface and into the slag. The reaction of FeO with C forms CO gas, and this gas generated in the bath gives rise to the boil. Maximum cleanliness of the steel demands a high degree of oxidation and a hot, active bath. Oxygen blown into the bath is of great assistance in attaining these ends.

The reactions taking place in the bath of the basic electric-arc furnace during the oxidation period are similar to those in the basic open-hearth, except that the electric-furnace bath can be made hotter (hence, there is more chance of phosphorus reversion unless the slag is strongly basic). Also, there is no continuous supply of oxygen to the bath as from the open-hearth flame.

When the charge has been melted completely under the conditions described, a preliminary sample is taken for chemical analysis and any additional materials required are added to promote further oxidation and adjust the basicity of the slag. If the oxides with acid properties (SiO_2 , P_2O_5 , Fe_2O_3 , etc.) are in excess of the oxides having basic properties, (CaO , MnO , MgO , FeO , etc.), the slag is an acid slag, while a basic slag is one having an excess of basic oxides. If the total amount of

basic oxides balances that of the acid oxides, a neutral slag is formed. The lime-silica ratios (the so-called "V" ratios) are used generally in calculating the basicity of slag. If the "V" ratio is greater than 2.0, the slag is "basic;" from 1.0 to 2.0 it is semi-basic, and if less than 1.0 it is considered acid. In the process described, the slag test should show a lime-silica ratio of from 2.2 to 2.8. Several methods are used for the above calculation, three of which are as follows:

1. Lime-silica ratio = $\frac{\% \text{ CaO}}{\% \text{ SiO}_2}$
2. Corrected ratio = $\frac{\text{CaO} - 1.6 \text{ P}_2\text{O}_5}{\text{SiO}_2}$
3. Corrected ratio = $\frac{\text{CaO}}{\text{SiO}_2 + 0.634 \text{ P}_2\text{O}_5}$

Electric-furnace steel may be made by a single slag process; the slag is first oxidized as described and then made reducing by adding the proper materials during the refining period. The usual practice with the cold-melt process is to use a double-slag method, an oxidizing slag followed by a reducing slag. If desired, it is also possible to use a neutral slag in case it is necessary to maintain the bath without further refining.

Refining—In the double-slag method the original slag, with its oxidation products, is slagged off or removed from the surface of the bath by cutting off the electric power to the electrodes, raising the electrodes, back-tilting the furnace slightly, and then raking the slag out through the charging door with wooden or steel rabbles. The original slag must be removed thoroughly to prevent delay in making up the second slag and reversion of any elements from slag to metal.

The materials used in making up the second or reducing slag are burnt lime, fluorspar, and silica sand, with powdered coke to supply carbon for forming calcium carbide. Typical proportions are 5 to 8 parts of lime, $\frac{1}{2}$ to 2 parts of fluorspar, 1 to 2 parts of coke, and $\frac{1}{2}$ to 1 part of silica sand. The above amounts are premixed in proportions determined by experience. Sufficient sand and fluorspar should be used to flux the lime quickly. Coke usually is added after the slag becomes fluid. Very often, small amounts of crushed ferrosilicon also are added. In producing low-carbon grades of steel, under 0.12 per cent carbon, a lime-silica, a lime-alumina, or a modified carbide slag containing less coke, is used.

The object is to form as quickly as possible a strongly reducing slag containing calcium carbide, and maintain it through the refining period. The presence of carbide may be detected readily by the odor of acetylene generated when a slag sample is wet with water that reacts with CaC_2 to form this gas. Carbide cannot exist in the presence of oxides reducible by carbon; therefore, a carbide slag is free of such oxides. A carbide slag acts to return reducible oxides such as those of manganese, chromium, vanadium, tungsten, iron, etc., from the slag to the metal; consequently, such oxides may be added for direct reduction as soon as the carbide slag is formed. The slag also serves to reduce the oxides in the bath and facilitates the removal of sulphur as calcium sulphide. The reactions proceed according to the following chemical equations:

Desulphurization is aided by a high manganese content, by the addition of lime and fluorspar, by agitation of the bath, and by high temperature. If very low sulphur is required, sometimes two carbide slags may be necessary. The carbide slag should be completely shaped up 20 to 40 minutes after the first slag has been removed. The carbide content of the slag is kept to a relatively low figure for the lower carbon heats, and, for very low carbon heats, silicon can be substituted for coke in the slag to prevent carbon pick-up by the metal.

Lime-alumina slags are made from lime and aluminum in the form of shot and/or granules. Calcium aluminate is formed, which both desulphurizes and deoxidizes the bath. Some of the deoxidation of the bath is done by the metallic aluminum before it oxidizes and combines with CaO as calcium-aluminate.

The steel should not be held under the second slag any longer than is absolutely necessary. As soon as results of the last preliminary analyses are reported, the necessary additions are made to the bath for adjustment of the carbon and alloying element content. The additions of alloying elements must be made in quantities sufficiently small to prevent chilling of the bath. When all of the additions are in solution, the slag is again shaped up and ferrosilicon is added. Final additions of aluminum for grain-size control usually are made just before tapping. The aluminum is put into the furnace, tied on the end of long bars to insure getting it through the slag into the bath. About one-half of the aluminum usually is added to the stream of metal in the spout as the heat is being tapped into the ladle. The furnace is tapped usually from 10 to 15 minutes after the final shaping of the slag and additions of ferrosilicon and aluminum have been made.

Induction Stirring—In the last few years, there has been considerable interest in stirring of the steel bath by electric induction. The original development occurred in Sweden, and two large furnaces in the United States are now equipped with the Swedish type of inductor stirrer. At present, an installation is being made utilizing a rotating-type stirrer developed in the United States.

In the Swedish design, an inductor constructed of steel laminations, in which is imbedded a two-phase winding, is installed under the bottom of the furnace. In order to permit penetration of the magnetic flux and to minimize bottom heating, the carbon-steel bottom plates ordinarily used are replaced by austenitic stainless-steel plates, which are treated theoretically as an air gap. A special generator and exciter is provided to produce two-phase current at a frequency of approximately $\frac{1}{2}$ cycle per second. During operation, a magnetic flux is produced in the form of a moving field. This moving magnetic field, reacting with a field induced in the bath, causes the bath to flow at a low rate of speed across the bottom of the hearth. Thus, a stirring action is obtained.

With the type of stirrer developed in the United States, a two-pole electromagnetic rotor is revolved underneath the furnace by a motor-and-gear mechanism. The rotor is excited by current from either the shop supply or a special generator. This causes a movement of flux across the bottom of the furnace, the bottom plates of which are made of austenitic stainless steel. In turn, this induces a movement in the molten steel bath similar to that previously described.

It has been proved that with induction stirring the segregation of alloying elements is greatly minimized. The temperature of the bath is much more uniform. It has also been demonstrated that, due to the movement

of the steel, the interface contact between the slag and the steel is greatly improved, with less time required to obtain the necessary metallurgical reactions.

Tapping—In tapping a heat, the electrodes are raised to the maximum height after the power is shut off, the tap hole is opened and the furnace is tilted by a control mechanism so that the steel is drained from the furnace into a ladle set on the pit side of the furnace. The slag comes after the steel and serves as an insulating blanket during tapping. A clean, round tap-hole and a clean, smooth tapping spout reduce the possibility of having a ragged, easily oxidized stream when tapping into the ladle.

LADLE, MOLD AND POURING PRACTICES

Ladle Practices—After all the molten steel in the furnace has been drained into the ladle, the ladle crane moves the ladle to the pouring platform where the steel is poured into molds. Both the ladle and pouring practices are practically identical with open-hearth practice, except both the inner and outer linings of the ladles are constructed of first-quality fire brick and special precautions are taken in setting the nozzles and stoppers because of the higher tapping temperatures employed in electric-furnace practice and the closer control desired for most electric-furnace products. The steel may be re-ladled (i.e., poured from one ladle into another) before teeming to insure the proper mixing of the alloys and reduce pouring temperatures.

Mold Practice—When the steel is ready to be poured, it is teemed into carefully prepared molds. Molds of the big-end-up type are used generally for the killed electric-furnace steels, while rimmed steels are poured into the conventional big-end-down molds. Shapes and sizes of molds vary considerably, depending on the steel being produced and the size and shape of the product. Round, square, and rectangular molds with smooth or fluted inside surfaces may be used.

The molds are scraped carefully, cleaned, coated with mold coating, preheated (if necessary), and all dirt is siphoned out after the hot tops have been set—about 30 minutes to 45 minutes before the heat taps. Each shop has a variety of different mold coatings and mold practices that have been developed for the particular grades of steel being produced. For instance, steel has been poured into clean uncoated molds, as well as molds coated with tar, salt brine, lime slurry, resin smudge, acetylene smudge, molasses, lamp black, oil, graphite, aluminum paint, and various other coatings.

Pouring Practice—Either of two pouring practices may be employed, the direct or the indirect. The former practice is accomplished by raising the stopper rod and allowing the steel to run directly into the mold from the ladle. In the indirect method, the steel is allowed to run through a refractory funnel and runner (as in bottom pouring). Basket pouring, a modification of indirect pouring, utilizes a small intermediate ladle which is filled from the large ladle. When the small ladle is filled, the nozzle in its bottom is opened, allowing the steel to run into the mold or molds through one or more openings or nozzles in the bottom of the basket. The purpose of indirect pouring is to reduce the splash in the bottom of the mold by eliminating the high ferrostatic pressure in the ladle, with the view of reducing scabs and other defects on the ingot surface. The theory justifying basket pouring is based on the premise that nonmetallic inclusions in the steel rise rapidly through relatively short distances at higher temperatures; thus, in conjunction with tapping the heat hot, inclusions rise out of the steel in the lower area of the

ladle before that steel issues from the bottom to fill the basket, and also rise in the basket while the molds are being filled.

Regardless of the pouring practice, the molds are filled slowly at first until the pool of steel on the bottom of the molds is about 6 inches deep, and then a full stream is permitted. When a conventional brick hot-top is used, a full stream is maintained until the steel rises to the bottom of the hot-top, at which moment the stopper is lowered to shut off the stream to permit the steel to freeze at the junction between the mold and hot-top, after which more steel is poured to fill the hot-top. When using a hot-top which seals the junction, the stream is permitted to flow full until the hot-top has been filled.

If the junction does not seal, steel will leak out and run over the top of the mold. The blocks supporting the hot-top are knocked out immediately after the junction seals to prevent "hanger cracks" in the ingot. Burnt lime, straw, brick dust, or manufactured hot-top covering materials are used on top of the molten metal in the hot-top to hold the metal in a molten condition long enough to fill up the shrinkage cavity in the ingot.

The ingots usually remain at the pouring platform for a predetermined time, to permit solidification of the ingot, usually in the range 1 to 2 hours, depending on the size of the ingot. They are then sent to the stripper, enroute to the rolling mills or forge department.

Repairs to Furnace Bottom and Banks—After the furnace is tapped, it is tilted back to its stationary operating position, the doors opened to permit smoke and fumes to clear out, and the furnace is inspected for damaged areas on the banks, bottom, roof and around the tap hole, or any other location where repairs may be needed; also for furnace skulls. The reducing slag cuts the basic lining and it usually is necessary to make up the "cinder line" where it has been eroded by the slag. If the refractory lining requires repairs, the patching is done immediately to allow the material to be sintered into place by the heat of the furnace.

Electrode Adjustments—If the electrodes are not sufficiently long to finish the next heat, there will be a delay during the making of the heat while the necessary adjustments are being made to the electrodes. The usual practice, therefore, after making repairs to the furnace, is to run the electrodes down until they are a short distance from the bottom to enable the operator to decide how much longer the electrodes will last. Adjustments are made either by adding new sections to the tops of the present electrodes or by allowing the electrodes to slip down through the holder to the desired position as the holder is raised, provided there is sufficient electrode extending above the holder to permit this to be done.

SLAG CONTROL IN THE BASIC PROCESS

The preceding discussions on slags indicate that slag control is a very important factor in electric-furnace steel production. The electric-arc furnace permits the slags to be controlled to meet almost any desired characteristic, a fact that is the real basis of the flexibility of the arc furnace.

As pointed out, the function of the melt-down slag is to oxidize carbon and phosphorus out of the steel and to remove some sulphur and nonmetallic substances. The lime-silica ratio should be between 2.2 and 3.0. The iron-oxide content of the slag varies with the carbon in the steel at the end of the boil, and may range from 13.0 to 20.0 per cent for medium-carbon steels. A good basic, melt-down slag in the electric

furnace is similar to a good open-hearth slag. A typical composition of a melt-down slag is as follows:

Constituent	Per Cent
Lime, CaO	40.9
Silica, SiO ₂	13.4
Iron Oxide, FeO	14.8
Alumina, Al ₂ O ₃	3.5
Magnesia, MgO	8.2
Manganous Oxide, MnO	12.7
Phosphorus Pentoxide, P ₂ O ₅	0.6
Sulphur, S	0.1

Lime-silica ratio and iron oxide content can be estimated from the appearance of slag "pancakes," and a skilled operator can judge these values very closely. A "pancake" is a slag sample prepared by pouring molten slag into a small, flat iron dish possibly 4 inches in diameter and ½ inch deep. In solidifying, the "pancake" acquires visible markings characteristic of its composition.

The refining slag removes dissolved oxides from the bath, protects alloy additions from oxidation, and removes sulphur. This slag is gray to black in color, is highly carbidic, and disintegrates or slakes to powder upon cooling. A typical composition of such a chemically reducing carbidic refining slag is as follows:

Constituent	Per Cent
Lime, CaO	67.8
Silica, SiO ₂	22.4
Iron Oxide, FeO	0.5
Alumina, Al ₂ O ₃	0.5

Magnesia, MgO	6.9
Manganous Oxide, MnO	0.2
Sulphur, S	0.3
Calcium Carbide, CaC ₂	1.5
Chromium Oxide, Cr ₂ O ₃	0.4

It is essential that furnace doors and openings be closed tightly if a good reducing slag is to be maintained. If a heat is too hot, the carbidic property of a slag will be lost very quickly. The carbon pick-up from such slags is fairly high and close checking must be maintained.

With low-carbon steels (0.15 per cent carbon or less), the carbide slag is modified by using a higher lime and lower coke ratio. In making low-carbon heats of 0.08 per cent carbon or less, crushed ferrosilicon or aluminum is substituted for carbon in the slag, forming calcium silicate or calcium aluminate.

Following is a typical composition of a lime-silica slag with no carbon added:

Constituent	Per Cent
Lime, CaO	57.9
Silica, SiO ₂	27.5
Alumina, Al ₂ O ₃	3.7
Iron and Manganous Oxide, FeO and MnO ..	1.0
Magnesia, MgO	7.7
Chromium Oxide, Cr ₂ O ₃	0.3

The above slag is white and, when cooled, will disintegrate to a powder. For 0.12 per cent carbon and lower stainless-steel heats, lime-silica and lime-alumina slags are used because they are carbon-free and easy to manage.

SECTION 4

THE ACID ELECTRIC-ARC FURNACE PROCESS

The acid electric-furnace process is, as previously mentioned, employed chiefly for the production of steel for castings by the foundry industry. Four major variations of the acid process are used: (1) partial oxidation, (2) complete oxidation (with a single slag), (3) complete oxidation with silicon reduction, and (4) double-slag practice.

Partial oxidation practice is used chiefly to produce low-priced steel castings that do not require any acceptance tests other than superficial surface inspection, because it is the cheapest method of making steel for such castings. The double-slag process is employed where it is desirable to have positive control to keep the FeO content of the finishing slag to a low value (about 10 per cent). Silicon in the slag can be reduced to enter the metal in acid-electric practice, and this procedure is employed in European practice but is not generally followed in this country.

The great majority of all American steel foundries employ the complete-oxidation process, and this method will be taken as the basis for the ensuing discussion.

With the exception of selection of scrap (which must have a low phosphorus and sulphur content), the melting down of the charge in the acid electric furnace is similar to that of the basic electric furnace. As with the basic electric furnace, the electrodes melt the scrap and bore their way through to the hearth of the furnace. If the pool of molten metal formed on the bottom does not cover sufficient area to extend beyond the area covered by the electrodes, the arc will act on the sand in the hearth of the furnace. The conductivity of a non-metal increases with temperature; consequently, the furnace hearth is a fairly good conductor of electricity

if it is hot. This working on the hearth or boring a hole into the hearth by the electrodes is called "pulling bottom" and generally is indicated by the appearance of white smoke accompanied by bright yellow flames around the electrode ports. When this occurs, the electrodes should be raised out of the charge and enough clean scrap added and melted to form a pool extending out from under the electrodes. If enough heavy scrap is used and is packed compactly enough on the bottom of the furnace, there is very little danger of pulling bottom.

Working the Heat—As soon as the charge is melted or nearly all melted, it is time to start working the heat. A little iron ore and silica sand should be spread over the bath at this time. If, as is often the case, a high percentage of returned foundry scrap is charged, very little silica sand need be added, because the oxidation of silicon and manganese in the scrap will form almost enough slag. Some iron also will be oxidized in melting down, forming FeO which will contribute to the slag. Enough slag-making material should be added to each heat to form a layer covering the metal at least ½ of an inch thick.

Although such a thin layer of slag may cause some difficulties, it is never advisable to have more slag on the metal than necessary at any time, because this will slow down the deoxidation of the steel. If "slag" (the term often used for silica sand in acid furnace practice) is not added, the bath will take silica from the hearth.

Slag samples taken from the furnace at melt-down should have a glassy, black color, indicating a high iron-oxide (FeO) content, which is necessary if a boil is to be expected later. A sample of the metal should be

taken from the furnace at the same time and the carbon content determined. The carbon content after melt-down, as in the basic process, should be higher than the carbon desired in the finished steel after it has been killed by additions of silicon and manganese near the end of the heat. The excess carbon will be removed by the boil.

If the slag test taken from the furnace has a brown or greenish color instead of black, it is an indication that there is insufficient FeO present. Ore is then added shovel by shovel-full until a black slag results. If the charge is made up of a large percentage of returned scrap, the ore should be added before all of the scrap is melted. The FeO added in this way will be taken up by the bath and the oxygen will react with silicon and manganese in the melting metal to form silicon dioxide (SiO₂) and manganous oxide (MnO), respectively. Because these oxides are of lower specific gravity than the molten metal, they will rise to the top of the bath, and because of their chemical affinity for each other—one being an “acid” and the other a “base”—they will unite to form slag. The chemical reactions are as follows:

The silicon and manganese must be oxidized before the carbon in the molten bath can combine with more oxygen from the ore to form the “boil.” The best practice is to oxidize the silicon and manganese while the bath is comparatively cold because high temperatures favor the combination of carbon and oxygen.

After the bath is covered with a black or oxidizing slag and the carbon content is high enough, the temperature should be increased until the steel is hot enough to boil. The “boil” is the reaction between the carbon and oxygen dissolved in the steel, and is necessary in the manufacture of clean, high-quality steel. These elements combine, when a certain temperature is reached, to form carbon monoxide, a gas:

Enough ore and carbon should have been in the bath, either naturally or by additions, to maintain the boil for at least ten minutes. A sample of the metal is taken from the bath and the carbon determined by a fracture test or by some rapid analytical test.

The intensity of the boil diminishes gradually as the oxygen in the metal is reduced. During this period, the slag is changing color continually and when it reaches a pea-green stage and has thickened up enough for a spoon, stirred through the slag, to pick up small lumps of slag, the steel has been deoxidized as much as possible by the carbon reaction. A carbon test is then taken and the carbon adjusted to the desired content. Silicon and manganese should then be added as ferroalloys for de-oxidation and the heat tapped soon after they are melted completely and diffused through the bath.

The temperature at which the steel is tapped from the furnace depends largely on the size of the castings to be poured and the equipment for handling the molten metal. If poured into many small castings the steel must be very hot (possibly 3200° F by optical pyrometer), while it may be from 150° to 200° colder when tapped from the furnace if the steel is poured directly from a large ladle into a mold for a large casting.

The preceding discussion refers specifically to production of plain or carbon steel for casting. Alloy cast steels are coming more and more into use, and present a new problem. Fortunately, three of the alloys commonly used in steel-foundry practice, copper, nickel and molybdenum, can be added at any time without loss due to oxidation and subsequent absorption by the slag during the steelmaking process. If these alloys are not added with the cold charge, they should be added from 15 to 30 minutes before the heat is tapped to give ample time for their solution and uniform distribution throughout the bath of molten metal.

When the steel ordered calls for manganese in excess of 1.25 per cent, it is very difficult to hold it in the metal under an acid slag. It is, therefore, advisable at times to add lime to the slag before tapping, thus decreasing its acidity and ability to absorb manganese.

Chromium presents a problem, as it is easily oxidized. It usually is added to the bath after the steel has been deoxidized (just after the final silicon addition). It usually is added as ferrochromium containing about 68 per cent chromium, 6 per cent carbon, and the balance iron.

Alloys such as aluminum, titanium, zirconium, vanadium and boron are added in the ladle. The common practice is to add these alloys in paper sacks, thrown into the ladle as the steel is being tapped so that the sack hits the metal stream.

SECTION 5

INDUCTION ELECTRIC-FURNACE PROCESSES

In most steel plants using induction furnaces, the melting procedure is essentially a crucible or “dead-melt” process. The charge is selected carefully to produce the composition desired in the finished steel with a minimum of further additions except, possibly, small amounts of ferroalloys as final deoxidizers.

The charge may consist of a single lump of metal, a number of small pieces of selected steel scrap, or even turnings or other light scrap with which is mixed a moderate amount of larger pieces to provide initial conditions which are favorable to the generation of heat. The charge is collected in pans placed on the working platform and either is dropped into the furnace through the top opening by tipping the pan, or by raking the pieces out of the pan and into the furnace. If the charge consists of pieces of scrap of varying size, the larger pieces are charged first, and the smaller pieces are packed about them as closely as possible. Even with the closest packing it is sometimes necessary to add some of

the charge as the melting progresses. As a rule, no re-fining is attempted in acid-lined furnaces, and it is seldom tried in a basic-lined furnace. If the furnace is equipped with a tight cover over the crucible, very little oxidation occurs during melting. Such a cover also serves to prevent cooling by radiation of heat from the surface of the molten metal. Hence, from the standpoint of heat loss, the use of a slag covering to protect the metal is unnecessary. Slags are being used successfully both during melt-down and refining, in special cases.

Melting the Charge—As soon as the furnace is charged, the switches admitting the primary high-frequency current to the coil of the furnace are closed. Immediately, the rapidly changing magnetic field at high flux density generates heavy secondary currents in the charge which are converted into heat by the electrical resistance of the charge itself. This heat is developed mainly in the outer rim of the metal in the charge, but is carried quickly to the center by conduc-

tion. Soon a pool of molten metal forms in the bottom, causing the charge to sink and at this point, any of the charge remaining is added. The current exerts a strong motor effect upon the liquid metal, which accelerates the melting by washing the still-solid part of the charge with molten metal, thoroughly mixing the metal as it is melted. This motion of the metal continues after all the charge is melted, in eddies giving the bath a convex surface, and varies in intensity with the power input. As the convex surface is not a favorable condition for slag treatment, the power input always is decreased to flatten the convexity and reduce the circulation rate when refining under either an oxidizing or a reducing slag. The flow of the liquid metal, even though less vigorous, then becomes a favorable condition, accelerating the purification reactions by constantly bringing new metal into close contact with the slag. When no purifying is attempted, the chief metallurgical advantages of the process are attributable to the stirring action, which promotes the uniformity of the product, the control over the super-heat or temperature above that of the melting point, and the opportunity afforded by the conditions of the melt to control deoxidation through proper additions. As soon as the charge has "melted clear," and refining actions have ceased, any objectionable slag is skimmed off, and the deoxidizers or other necessary alloying elements are added. When these additions have melted and become diffused in the bath, the power input may be increased to bring the temperature of the metal up to the point most desirable for pouring. The current then is turned off and the furnace is tilted for pouring, either directly into ingot molds or into a ladle, the ladle being used with the larger furnaces. As soon as pouring has ceased, any slag adhering to the wall of the crucible is scraped out and the furnace is righted for charging again.

Advantages of Induction Melting—Induction furnaces are relatively low in cost, as compared to other types of melting units and, as a result, several furnaces for operation from a single frequency changer can be installed at little extra expense, and furnaces of various capacities can be used as required or individual furnaces can be retained for making melts of special alloys without danger of contamination or the necessity of making "wash heats." Among other advantages, there is very little heat radiated from the furnaces as they are water cooled, and there is practically no noise attending their operation.

This type of furnace requires about 650 kwh. of input power per ton of molten metal and heats are melted in about an hour to an hour and fifteen minutes.

For the melting of high-alloy chromium steels, there is quite an advantage in using the induction type of furnace because the highest temperature to which the scrap is subjected is that of the bath. In the arc furnace the temperature of the arc may be 7200° F (approximately 4000° C) which vaporizes the chromium in ex-

posed scrap, causing a loss of up to 15 per cent of this element. Since the capacities of induction furnaces have been limited to about three tons, the popular range being from 200 to 2000 pounds, this type of furnace is used only for small heats.

In remelting alloy-steel scrap in these furnaces, it is possible to make melts in less time than with other methods of melting and this minimizes loss of valuable alloying elements by oxidation. Heat is induced in the metal by eddy-currents due to circulating electrical currents of high magnitude. Where heat must be absorbed from radiant energy, as in other types of furnaces, there is a limit to the rate at which the metal charge can absorb heat.

Molten metal in an induction furnace is caused to circulate automatically by electromagnetic action. When alloy additions are made to a molten charge, the stirring action results in creating a homogeneous product in a minimum of time. Due to the turbulent action in the bath and the skim slag, it is possible to get accurate temperature readings with a radiation pyrometer and, by electronic control, hold the bath temperature within $\pm 5^\circ$ F. This is an advantage when pouring small castings, when thirty minutes or more are required to empty the furnace.

Up to a few years ago, the standard equipment used to supply power to these induction furnaces was a rotary motor-generator set, which supplied a frequency in the neighborhood of 1,000 cycles. Lately, mercury-arc frequency changers have been used which have several advantages; the efficiency is higher than that of motor-generator sets and the static device presents no problems in vibration or air ventilation, and the cost is kept to a minimum. Another feature of this type of melting is that the frequency output is determined by the output circuit. If the frequency characteristic of the circuit changes during operation, the mercury-arc inverter automatically will supply the frequency required by the melting circuit.

Special alloys can be produced by melting in a vacuum, or under pressure in an inert-gas atmosphere, by enclosing the entire coreless induction furnace and mold in an airtight container which can be evacuated or put under pressure. When melting is complete, the molten contents of the furnace are poured into the mold; this is accomplished entirely by control elements outside the container that make it possible to tilt the container for pouring the furnace without opening the container. After the metal solidifies, the container can be opened for emptying the mold and recharging the furnace. Section 6 of this chapter gives further details on vacuum and atmosphere melting.

Disadvantages of Induction Melting—Limited holding capacity and inability to control the composition of the melt except through the careful selection of scrap appear as the chief drawbacks of the induction furnace, from metallurgical and commercial viewpoints.

SECTION 6

VACUUM AND ATMOSPHERE MELTING

In recent years, methods have been developed for commercial melting of metals and alloys of certain types in vacuum or under controlled atmospheres. Vacuum-melting techniques are employed in the case of some steels to obtain improved physical and mechanical properties unobtainable in any other way. Some other metals, notably titanium, cannot be melted successfully at all except under such conditions.

Vacuum furnaces have been heated by the electric arc,

by electrical resistance, by gas, and by electrical induction. However, only electrical induction has been used on any sizeable scale for melting steels. This latter method employs a high-frequency coreless induction unit (see Section 5), enclosed in a container or tank which can be either evacuated or filled with an atmosphere of any desired composition and pressure. Provision is made by suitable electrical and mechanical mechanisms and controls for making additions to the

melt and for tilting the furnace after melting to pour its molten contents into the ingot mold which also is enclosed in the tank or container. Most of the vacuum furnaces in operation in the United States are of one-quarter and one-half ton capacity, but larger units melting up to three tons have been proved practicable.

The electrical frequency employed by the coreless induction furnaces for vacuum and atmosphere melting depends upon the capacity of the melting unit, as it does in the case of such furnaces used in ordinary melting processes. Most of the crucibles for vacuum melting have basic linings.

While vacuum melting often has been employed simply as a remelting operation for very pure materials, it is more generally useful in those applications where some refining also is accomplished. Oxygen, nitrogen and hydrogen can be removed from the molten metal in vacuum melting as well as carbon when alloys having very low carbon content are being produced (i.e., some of the stainless steels).

The control of pressure and composition of the gas over a melt makes it possible to deoxidize the melt with carbon or hydrogen, both of which produce gaseous deoxidation products, thus preventing the formation of solid non-metallic inclusions in the finished steel. Also, when melting in a vacuum, the absence of nitrogen from the atmosphere over the melt prevents formation of nitrides and carbonitrides that appear in many steels and high-temperature alloys melted under ordinary atmospheric conditions. The exclusion of oxygen by vacuum melting prevents oxidation losses and permits very close control of the composition of alloys containing easily-oxidized components.

The volatility of certain alloying elements such as chromium, aluminum and manganese may result in high losses of these elements if they are added to steel under a high vacuum. These losses may be minimized

by replacing the vacuum with an inert gas as the atmosphere over the melt during the period when such additions are being made.

The entire subject of vacuum melting of steels is still in the relatively early stages of development. As work continues with this technique, it will be possible to compare the characteristics of metals and alloys melted under reduced pressure or controlled atmosphere with those of materials melted in air by ordinary methods. Vacuum and atmosphere melting of steels and other ferrous alloys will grow in proportion to the need for metals possessing whatever special properties may be developed by these techniques.

Chapter 17

DUPLEX AND TRIPLEX STEELMAKING PROCESSES

SECTION 1

DUPLEX PROCESSES

Definition—The term *duplex process* may be applied to any combination of two processes for manufacturing steel but, in the United States at least, custom has restricted the unmodified term to mean only a combination of the acid Bessemer converter and the basic open-hearth processes, in which the latter plays the part of a finishing process. Briefly, the duplex process consists of blowing molten pig iron in the Bessemer converter until the silicon, manganese and most of the carbon have been oxidized, and then transferring this semi-finished metal to a basic open-hearth furnace where, through the agencies of iron oxide and lime, the phosphorus and the remainder of the carbon are oxidized and lowered to desired limits. The steel is then finished, recarburized and deoxidized as in the usual open-hearth practice.

Tilting Open-Hearth Furnaces—Open-hearth furnaces of the tilting type are especially adapted to the duplex process and the major portion of the tonnage of duplex-process steels is made in such furnaces. This type of open-hearth furnace was originally designed for purposes other than duplexing. The first tilt-

ing open-hearth furnace was placed in operation in 1889 at the Steelton Plant of the former Pennsylvania Steel Company by H. H. Campbell. This antedated the introduction of the duplex process by more than ten years.

The Campbell tilting furnace was introduced as a means of readily using high percentages of pig iron and avoiding some of the operating difficulties then inherent in stationary furnaces. The furnace proper rested on rollers arranged in a circular path, providing rotation on its longitudinal axis. With this arrangement, fuel could be fired even when the furnace was in tipped positions. The advantages claimed by Campbell for the tilting feature were the ease of removal of large slag volumes when high-pig-iron charges were used; the elimination of delays and difficulties in maintaining tapholes, the taphole being located above the level of the bath; the greater ease in repairing bottoms or hearths because the furnace could be drained by tilting; and finally, the greater ease of maintaining the backwalls.

The Campbell furnace was shortly followed by the Wellman tilting furnace, in which the furnace proper

FIG. 17-2. This illustration shows the 200-ton tilting basic open-hearth furnace of Figure 17-1 in tapping position.

rolled forward on a horizontal track, necessitating fuel and air shut-off when the furnace was in tipped position.

Figure 17-1 shows a typical modern tilting open-hearth furnace of the Campbell type in normal operating position; Figure 17-2 shows the same furnace in tilted position during tapping.

DUPLEX PLANT LAYOUT AND EQUIPMENT

Description of Duplex Plant—In a plant to make steel only by the duplex process, Bessemer capacity should balance tilting-furnace capacity, and the converters should be in close proximity to the tilting furnaces to facilitate transfer of metal from one to the other. An exact balance is difficult to plan in advance, for the time the steel is held in the open-hearth furnace varies with the grade of steel being made. For this reason, it is better to arrange for the production of some Bessemer steel along with the duplex production in order to utilize the equipment more fully. Also, the relative number of furnaces necessary to maintain a workable balance depends somewhat upon the tonnage to be produced. For example, one 20-ton converter serving a 200-ton tilting furnace would be an unsatisfactory combination, as interruptions in the operation of either would delay the other. But a combination in which three 25-ton converters serve three 200-ton tilting furnaces gives a well-balanced operating unit for the continuous production of steel.

In addition to the required number of furnaces and converters for the steel production desired, it is generally considered necessary to have at least two hot-metal mixers. Adequate facilities for transfer of iron to the converter and of blown metal from the converters to the open-hearth floor must be provided in order to prevent delays in furnace charging.

In general, all other facilities provided for a scrap-melting shop, including facilities for ladle repair, mold preparation and slag disposal, must be provided. The requirements for charging machines, boxes and buggies

are not so heavy as in a scrap shop. On the pit side, pouring facilities must be particularly well organized in order to tap, pour and move the heats on the rapid schedules attained in duplex operation.

In addition to the auxiliary equipment necessary for an open-hearth shop, much of the apparatus necessary for a Bessemer shop must also be provided. In this connection blowing equipment, vessel-tilting machinery, vessel and vessel bottom-repair equipment are the most important.

The application of the principles of the duplex process to the making of steel has resulted in various modifications. Some of the most common examples will be described in the following sections, using figures based on practices in typical plants.

A. CONTINUOUS PROCESS MAINTAINING A DOMINANT POOL

This description will cover a process developed in the South for the manufacture of steel in basic-lined tilting open-hearth furnaces, using hot metal produced in blast furnaces charged with a blended iron ore of relatively high phosphorus content. Typical contents of various constituents of the fractions of such a blended ore may be as follows:

Constituent	Percentage Content		
	Coarse Fraction	Medium Fraction	Sinter Fraction
Moisture	3.40	5.23	1.50
Iron (Fe)	43.23	49.10	58.33
Silica (SiO_2)	11.00	6.92	6.57
Alumina (Al_2O_3)	2.61	2.23	2.58
Lime (CaO)	9.50	5.72	4.98
Manganese (Mn)	0.13	0.09	0.09
Phosphorus (P)	0.25	0.19	0.19

Hot metal produced from ore of this composition by the blast furnaces may be expected to have a composition falling within the following specification ranges:

Element	Per Cent
Silicon	0.70 - 1.00
Sulphur	0.075 maximum
Phosphorus	0.40 - 0.60
Manganese	0.13 - 0.30

The basic tilting open-hearth practice developed to use high-phosphorus hot metal of this composition for steel-making requires the following essential steps: the maintenance of a **dominant pool** of metal in a tilting basic open-hearth furnace, adding approximately 80 per cent of the next succeeding heat in the form of blown metal from the acid-Bessemer converters, impregnating the basic finishing slag of the previous heat with the phosphorus contained by this blown metal, and then flushing the phosphorus-laden slag from the furnace.

One open-hearth plant employing this process consists of two shops with five and four tilting furnaces, respectively. Between these two shops is a converting department with one 1250-ton and one 650-ton mixer, together with three 20-ton acid-Bessemer converters. The location of the converting department lends itself to an operation with a minimum of delay in delivering blown metal to the open-hearth furnaces. In case of a delay in one shop, the blown metal generally can be delivered to one of the furnaces in the other. Blown metal is poured out of the converters on the open-hearth charging-floor level and is transported in 25-ton ladles mounted in trunnions on ladle cars. Metal is poured into an open-hearth furnace by tilting the ladle in its trunnions on the car.

The tilting open-hearth furnaces are of the Campbell type in which the furnace is mounted on rocker arms and rollers and can be tilted forward and backward about a horizontal axis. The axis of rotation of each of these furnaces is coincident with the center-line of the ports and rotation of a furnace does not interfere with firing. The framework is of much stronger construction than that for ordinary open-hearth furnaces in order to resist twisting stresses and vibration which would be very harmful to the brickwork.

Only that section of a furnace comprising the hearth, sidewalls, and roof is made tilting; all the ports and flues are stationary, and, together with the checkerwork, are of the same construction as in stationary furnaces. The clearance between the movable and stationary parts of the ports is kept very small by the use of water-cooled joints, in order to keep air and gas leakage to a minimum. On the pouring side, these furnaces have but one opening, a tapping hole located above the slag line and provided with a lip or spout for directing the stream of molten metal into the steel ladle. As in the case of stationary furnaces, doors for introducing the materials into the furnace are located on the front side. Slag notches are also located in the middle doors on the front side.

Preparing the Furnace for Charging—The process may be said to be continuous. When it is necessary to make repairs, the tilting furnace is thoroughly drained, the bottom and slag lines are made up, the ports are cleaned and repaired, and everything is made ready for the resumption of standard production. Of course, during operation the front and backwall must be attended to and such minor repairs made as are found necessary. Before any iron is blown in the converters, the preparation of a slag is begun by charging and melting down lime and oxides. Considerable care is given by the melter to the preparation of a good slag, for, as in all open-hearth work, the success of the process depends upon the slag.

Except for the first heats, there are from 25 to 35 tons of each 175-ton heat of steel retained in the furnace at each tapping; this forms what is referred to as the "dominant pool."

Cycle of Operations—When a ladle is filled with finished steel tapped from one heat, the steel in the ladle is covered with a blanket of slag which flows out of the taphole as the furnace is rolling back to an upright position. Most of the slag is retained in the furnace. When a furnace is completely upright, the slag level is below the taphole. As soon as tapping is completed, approximately 80 per cent of the next succeeding heat is immediately added to the furnace in the form of full-blown metal which usually consists of five "pots" or ladles full of blown metal totaling approximately 100 tons. The blown metal, being washed through the highly-basic finishing slag of the previous heat, is rapidly dephosphorized. This slag is then immediately poured off the washed metal over the foreplate into slag pots on cars on narrow-gauge tracks at basement level. The slag-making constituents, for refining the washed metal that is the starting point for the new heat, is then charged; these usually consist of burnt lime and oxides as required. From 1 to 1½ hours are required for the charged burnt lime and oxides to melt and form a suitable slag. When the slag is in proper condition, two pots or ladles of partially-blown high-carbon metal are added to supply the carbon necessary for working the heat. The refining period from time of the addition of the last partially-blown or high-carbon pot requires from one hour and thirty minutes to two hours and thirty minutes, depending upon the type of steel being produced.

In the blowing operation silicon, carbon and manganese are all practically removed when blowing a full-blown, low carbon or "soft" pot. The phosphorus content, due to the loss of carbon, silicon, manganese and some iron during blowing, is increased from an average of 0.50 per cent in the iron to around 0.55 per cent in the blown metal. The greater part of the silicon, along with some of the carbon and manganese are removed in blowing a high-carbon pot. A definite range of ferrous-oxide content of the slag is necessary for effective dephosphorization of the blown metal, and this is maintained by suitable additions to the bath of burnt lime, mill scale, ore and ferromanganese or ferrosilicon.

With this operation it is possible to produce steel ranging from low-metalloid grades to carbon tool steels.

Advantages of the Process—Considerable benefit is derived from the use of full-blown metal charges, eliminating contamination of the bath by undesirable alloys normally present in scrap. This is especially true when producing a low-metalloid heat.

One of the benefits derived from this process is a minimizing of reaction between slag and steel during tapping; more of this reaction occurs at tap in conventional stationary open-hearth practice. This advantage is made possible by plugging the taphole of the tilting furnace with bagging which holds until the slag rises above the hole while the furnace is being tilted. The only slag removed is that amount coming out after the ladle is filled and the furnace is being rolled back to an upright position. This provides a relatively thin blanket to prevent the steel in the ladle from freezing.

The process provides uniformity from heat to heat through the duplication of desired heat cycles. During all periods the fuel is not checked and little loss in temperature occurs. This is advantageous as regards the useful life of the roof and other brickwork of the furnace.

This process can be flexible in its use of charged materials. When, due to shortages of hot metal, increased percentages of scrap are required, the additional scrap may be charged in small amounts into several furnaces or may be confined to one furnace, although increasing the percentage of scrap charged does lengthen the heat cycle. The tilting furnace facilitates bottom repair in that the furnace may be tilted forward or backward to drain a hole which would have to be rabbled out in the stationary type of furnace.

Slag Composition—Composition of a typical refining slag and composition of the slag after the addition of the full-blown "soft" pots is as follows:

Constituent	Refining Slag (%)	Before Slagging Over Foreplate (%)
Ferrous oxide (FeO)	14.00	4.50
Ferric oxide (Fe ₂ O ₃)	8.60	5.50
Silica (SiO ₂)	9.75	12.50
Lime (CaO)	48.00	49.00
Magnesia (MgO)	4.00	4.00
Manganous oxide (MnO)	2.50	1.50
Phosphoric Acid (P ₂ O ₅)	8.00 - 13.00	10.00 - 20.00

The high-phosphorus slag obtained after the addition of the full-blown "soft" pots is diluted to some extent by the "kick-off" or flush slag resulting from the reaction at the time of addition of the partially-blown high-carbon pots of metal.

Deficiencies of the Dominant Pool Method—The most valid criticisms of the dominant pool method are that, (1) the tapping slag which remains in the furnace after a heat contains a high phosphorus content, (2) the pool of metal remaining in the furnace is likely to become too highly oxidized before the furnace is filled up again, (3) the fluxing materials for the next heat are charged on top of and float on the remaining pool, failing to give the beneficial effects that can be derived from a prolonged boil from lime charged on the bottom, (4) frequent examination of the furnace bottom is impossible with resulting long "bottom delays."

B. THE DRY BOTTOM OR SINGLE HEAT DUPLEX PROCESS

This duplex method is commonly used in northern United States at present, except where special conditions dictate continuation of the dominant pool method. It is a continuous operation with no week-end bottom-repair period. Several different practices of preparing the charge are used and local conditions are the factors that determine which practice shall be employed. The method is so flexible that all of the practices in use produce steel of satisfactory quality and quantity; consequently, only one dry-bottom practice is described.

The Charge—After the previous heat has been tapped, the furnace is turned into its normal operating position. The melter foreman examines the bottom and, if no repairs are necessary, orders the next charge from the Bessemer steel blower. The amount of limestone charged is determined by the grade of steel to be made. If a heat of rimmed steel is to be produced, 16,800 pounds of raw limestone will be charged for a 145 ton heat. If the heat is to be semikilled or killed, this amount is reduced to 11,200 pounds. As soon as the melter foreman has ordered the charge, approximately one-half of the limestone is charged on the furnace bottom and the furnace crew proceed with the slag line repairs to the front, back, and ends.

To produce an open-hearth heat of 145 tons, approximately 335,000 pounds of liquid pig iron are ordered for the converters. Two heats (blows) of 45,000 and 50,000 pounds each are blown simultaneously in the Bessemer converters and when they reach a point in the blow where the carbon content is between 0.10 and 0.20 per cent they are turned down and poured into one ladle. This ladle of metal is carried by an overhead crane and poured through a spout into the open-hearth furnace. After the first ladle of metal has been poured into the furnace, the remainder of the limestone is charged. The balance of the blown metal follows, there being three ladles in all.

After the last heat has been blown in the converters, liquid basic pig iron in amounts ranging from 35,000 to 47,000 pounds is brought from the mixers and charged into the open-hearth furnace. The unblown basic hot metal is used because its manganese content is higher than blown Bessemer hot metal, thus assuring a residual manganese in the charge comparable to that encountered in any regular open-hearth heat. Varying amounts of this metal are used to provide the initial carbon content of the bath necessary for different grades of steel. The amounts of blown metal, therefore, must obviously be adjusted so that the complete charge will total approximately 310,000 pounds.

There are three reasons for stopping the blow when the carbon content reaches 0.10 and 0.20 per cent; first, this eliminates the possibility of over-oxidation of the metal; second, the nitrogen content of the steel will be lower than in full blown metal; and third, it assists in producing a slag in the acid converter that is sufficiently thick (viscous) to minimize its carry-over to the basic open-hearth furnace.

A summary of the charge is as follows:

	Rimmed Steel (Pounds)	Semi-killed or Killed Steel (Pounds)
Limestone	8,400	7,000
Blown Metal	90,000	90,000
Limestone	8,400	4,200
Blown Metal	90,000	90,000
Blown Metal	90,000	90,000
Basic Hot Metal	40,000	40,000
Total Limestone	16,800	11,200
Total Blown Metal	270,000	270,000
Total Hot Metal	40,000	40,000

The difference between the 335,000 pounds of metal ordered from the mixers and the 310,000 pounds in the open-hearth charge is, of course, that portion lost during the blowing process.

Working the Heat—Approximately thirty minutes after the furnace has been completely charged, a test is taken and analyzed for carbon and manganese. This analysis indicates to the furnace crew the amounts of lump ore necessary to reduce the carbon to the desired point. All heats are charged to provide an initial carbon content about 40 "points" (0.40 per cent) above the tapping carbon, with the exception of certain grades for extra-deep-drawing applications. On these latter grades a much higher initial carbon is desired and provided because the increased ore additions necessary for the carbon reduction promote an active boil of the bath for a longer period of time and thus reduce the nitrogen content of the steel. The normal nitrogen content of steels made by the liquid-charge method is 0.006 to 0.008 per cent, while in standard basic open-hearth steels the range is 0.004 to 0.006 per cent. The additional bath activity described above, however, re-

duces the nitrogen content to the 0.004 to 0.006 per cent range, and it is this slight reduction in nitrogen content that permits steel made by the liquid-metal process to compete favorably on applications demanding a high degree of ductility and relative insensitivity to strain aging.

During the early working period of the heat, the lime boil takes place until the limestone charged on the bottom is thoroughly calcined and rises to the surface to form the slag.

When the bath has reached the necessary temperature, additions of lump ore are begun and proceed periodically throughout the working period as demanded. During this period chemical analyses are made for phosphorus and sulphur, and carbometer tests are taken to indicate to the furnace crew the extent of carbon elimination.

Pancake slag tests are also taken and additional burnt limestone or mill roll scale is added for the purpose of providing the proper slag consistency.

The heat is "worked down" in the same manner as any basic open-hearth heat, and when the desired carbon content is reached, a ladle is set on the tapping side of the furnace. The furnace is then tilted to permit the slag to rise above the tap hole and the metal to flow into the ladle.

Recarburizing material is usually kept to a minimum, the carbon being "caught on the way down." Deoxidizing materials, such as ferromanganese, silicon, aluminum, titanium, etc., are added to the ladle the same as in any other open-hearth heat.

The Slag.—The slag volume for steel made by this duplex process is less than on regular open-hearth steel, running approximately 6.5 per cent of the weight of the finished heat. The limestone charged is normally 90 to 95 pounds per ton of steel; this is possible because of the very low silicon content of the charge. No difficulty is experienced in the removal of phosphorus, except when a considerable amount of Bessemer slag is allowed to enter the furnace with the charge.

The average composition in per cent of tapping slag of a steel tapped at 0.09 per cent carbon and 0.17 per cent residual manganese follows:

SiO ₂	11.58 %	MnO	8.86
Al ₂ O ₃	1.16	CaO	41.50
TiO ₂	0.29	MgO	6.23
FeO	18.55	P ₂ O ₅	3.16
Fe ₂ O ₃	5.57	S	0.17

Heat time averages approximately four hours tap to tap.

C. COMBINATION SCRAP AND BLOWN METAL METHOD

This type of operation may be used in tilting-furnace shops, but is particularly adapted for use in plants that have stationary furnaces, yet desire to take advantage of the faster-melting duplex practice. Although many variations of the method are possible, depending upon local operating and economic conditions, the system described is one that has been very successful from a production standpoint in one of the eastern plants.

The practice employed is to charge the limestone, ore, scrap and hot metal as for a regular high-iron charge. After the slag flush is finished, the full-blown Bessemer metal is added in amounts of about 16 or 32 per cent of the total charge, and a second quantity of slag is flushed off. Satisfactory slag flushes are obtained when the blown metal is either 16 or 32 per cent of the total charge. The amount of ore charged is regulated to specific conditions, such as type of scrap, age of furnace, and carbon desired at melt down. The limestone requirements for the blown-metal heats are regulated by the amount of silica in the charge in the same manner as for regular high-iron charges. The fuel requirements for 16 and 32 per cent blown-metal heats are about 10 and 20 per cent, respectively, below those of high-iron-charge heats made in the same shop. The melting times for these two types of heats are approximately 10 and 25 per cent less than the corresponding high-iron-charge heats, but approximately 100 per cent longer than liquid-metal heats made by dry-bottom practice.

As soon as the melt-down is complete, the working of the heat and slag adjustments take place just as in dry-bottom duplex or scrap and hot-metal heats. When the analysis shows that the heat is ready to tap, additions are made as in other heats produced in a stationary furnace, the furnace is tapped out clean and the steel is deoxidized in the usual manner.

Table 17—I indicates the time-saving and corresponding increased production possible with this type of operation.

The quality of the steel made with this type of charge corresponds favorably to that of regular basic open-hearth steel.

ADVANTAGES AND DISADVANTAGES OF THE DUPLEX PROCESSES

In the northern district of the United States, the chief advantages of the duplex process are the increased

tonnage which it produces in a given time, and its freedom from dependence on purchased scrap. In the southern district, the duplex process also provides a method of manufacturing high quality steel from high phosphorus pig iron, and, in addition, produces a highly basic slag containing a high percentage of citric-acid-soluble P_2O_5 which is valuable as a soil conditioner. Thus, while the product is similar in quality and of the same grades as basic open-hearth steel, the time of the open-hearth operation is shortened by more than half. Whereas one open-hearth furnace will turn out an average of about fifteen heats in a week of melting scrap and hot metal or scrap and ore heats, the same furnace operated as a duplexing unit will produce about forty heats in the same period. This shortening of the time of heats saves fuel, and this factor, together with the elimination of the silicon in the converter slag, tends to prolong the life of the open-hearth furnace. The process does not require the use of scrap, an advantage when scrap is scarce and high in price.

The duplex process is capable of making any type of heat which can be made in a basic open-hearth furnace, but because of the ability of a scrap shop to recover alloys from scrap, most alloy steels are made in shops charging scrap rather than in duplex shops. On the other hand, where heats of low residual-alloy content are desired, a duplex shop is at a distinct advantage as compared with a scrap and hot-metal shop. In respect to flexibility, a duplex plant is in a far better position than one equipped only for scrap and hot metal because of the possibility of charging either scrap or blown metal, whichever is cheaper at the time. Naturally, a shop designed for duplex operation which changed over to scrap melting in order to take advantage of cheap scrap, would fail to melt the tonnage attainable on duplex operation.

In recent years, steel produced by the duplex process, according to the improved practices discussed earlier, has been applied to an ever-increasing number of uses for which basic open-hearth steel formerly was thought to be better suited. As knowledge increased as to the effects of relatively small amounts of various constituents of steel on its properties, it was established that the relatively higher nitrogen content of duplex steel (as compared with basic open-hearth steel) was the principal factor influencing its properties and resulting in certain disadvantages of that earlier duplex steel. The chief effect of the higher nitrogen content of the earlier duplex steel was to increase its susceptibility to strain aging. When these facts were ascertained, duplex steel-

making practices were altered and improved in a way which would consistently produce steel having a controlled nitrogen content but little greater than that of basic open-hearth steel, as indicated by the following figures showing the ranges of nitrogen content common to present-day Bessemer, duplex, and basic open-hearth steels:

Type of Steel	Average Nitrogen Content
Bessemer	0.012 to 0.020%
Duplex	0.005 to 0.008
Basic open-hearth	0.004 to 0.006

Because the chemical composition of duplex steel made by the improved practices approaches that of basic open-hearth steel, and can be controlled closely, it is understandable that the new duplex steel now can be applied to many purposes for which it once was considered less suitable than open-hearth steel.

The duplex process is now employed to produce many high-quality grades of steel for such applications as forged automotive crankshafts, seamless tubes, rolled sections for automotive-wheel rims, and other products ranging from high-grade thin flat-rolled materials to railroad rails. It may be noted that the slightly higher nitrogen content of duplex steels makes them somewhat harder than open-hearth steels of otherwise similar composition; this may be an actual advantage in a few cases, for example, in the manufacture of low-phosphorus steel for tin plate that must meet high-temper specifications.

The high-quality raw materials provided for successful duplex practice, coupled with the present satisfactory performance of the product, leads to the belief that further expansion will be made in application of duplex steel. The present status of basic open-hearth practice, wherein the charge material contains ever-increasing amounts of sulphur and unwanted alloys from scrap, may result in the wider use of the duplex process.

The principal disadvantages of the duplex process are the initial cost of providing a plant with both open-hearth and Bessemer facilities, and lower ingot yield brought about through the combined Bessemer and open-hearth conversion losses. The double conversion cost of producing steel by this method would also appear to place it in an unfavorable competitive position. Based on its higher rate of production, however, the seriousness of the initial cost is offset to a great extent.

SECTION 2

TRIPLEX PROCESSES

The term "triplexing" refers to a combination steel-making practice in which the same steel is processed successively in Bessemer, open-hearth and electric furnace with the usual aim being to produce a steel of electric-furnace quality.

Just as there are theoretically many possible duplexing combinations, as outlined earlier, so there are even more possible combinations of both acid and basic furnaces for the manufacture of triplex steel. However, only a limited number of these combined processes has been used for any length of time. The excessive maintenance cost of three furnaces, high cost of handling molten metal, and the excessive heat losses in handling have prevented the use of the process except under highly specialized conditions. Also, electric-furnace

steels have been produced by charging blown metal direct from an acid converter into a basic electric furnace to produce electric-furnace steel of good quality at a high rate. The knowledge that this is possible serves to illustrate the wastefulness of triplexing when, as in most cases, the same end can be accomplished by a duplex process.

Chapter 18

CASTINGS - STEEL AND IRON

SECTION 1

STEEL CASTINGS

Casting Compared with Other Forms of Shaping Steel—The process of making steel castings consists simply of pouring metal into a mold which is of the desired shape, dimensionally accurate and of sufficient stability to permit the metal to solidify in the exact shape of the mold cavity. Intricate and complicated castings of practically any desired shape or size, and for almost any particular application, can be made in this manner. The versatility of the foundry trade commands recognition throughout the industrial world, and design engineers in every field of endeavor have come to rely upon the utility of steel castings.

Mechanically, steel castings are considered inferior to wrought-steel products, and it is true that wrought steels do exhibit higher mechanical properties than cast steels, especially when the former are tested in the direction of rolling or forging. Moreover, cast structures, unless designed in strict conformity with the natural characteristics of metal solidification, sometimes contain internal defects or surface imperfections which may seriously affect serviceability and otherwise render them less dependable than a wrought-steel product. However, the casting of steel is the most direct method of producing a given shape and, for this reason, the method provides the basis for a key industry.

Tonnagewise, the steel-casting or steel-foundry industry would appear to be of minor importance, approximately two per cent of the total steel production per year being in the form of castings. However, few industries enjoy so prominent a role in the industrial and domestic development of the world as the foundry industry. Many articles, especially turbine shells, valve bodies, and machine parts are made by casting, not by choice, but because they cannot be made as readily by other processes. For example, valve bodies, exhaust manifolds, pump casings, and turbine diaphragms could be fabricated by other processes or from wrought products only with extreme difficulty and at a serious economic disadvantage. Also, cast structures are generally considered to be more rigid than their wrought counterparts.

Steel castings vary in weight from a few ounces to hundreds of tons and cover a multitude of designs and services. Latch castings for airplane cowls weigh less than four ounces, while one of the largest castings ever produced was a 240-ton casting for an armor press of 35,000 tons capacity. Castings for steel-mill service alone cover a very large field and include housings, gears, charging boxes, guides, blast-furnace bells, hoppers and cinder pots. Rolls for certain types of rolling mills are made of cast steel; because of the specialized foundry techniques employed in roll casting, the manufacture of rolling-mill rolls by casting is discussed separately and at length in Chapter 23. The transportation industry re-

lies upon castings for railroad and marine use, such as couplings, journal boxes, bolsters, frames, brake shoes, cylinders, housings, valves, crankshafts, engine beds and steam chests. These are but a few of the examples in everyday use and hundreds of other applications could be mentioned serving the chemical, petroleum, mining, excavating, agricultural, ceramic and construction industries.

Composition and Mechanical Properties of Cast Steels—The development of the mechanical properties of cast steels depends almost wholly upon heat treatment, and since the depth of hardening in carbon steels is limited, it follows that alloys in varying proportions must be added when high strength is required. This is especially true of castings with heavy metal sections. Nickel, chromium, manganese, molybdenum, and vanadium are alloys commonly added to cast steels. These are added according to the manufacturers' past experiences and heat-treating facilities. Table 18—I shows typical compositions and results of tension tests for some heat-treated cast steels.

MAKING STEEL FOR CASTINGS

Five types of furnaces are or have been employed by foundries for melting steel. These are: (1) the direct-arc electric furnace; (2) the open-hearth furnace; (3) the pneumatic converter; (4) the electric-induction furnace; and (5) the crucible furnace. The pneumatic converter and the crucible processes, formerly of importance, have now been supplanted almost entirely by electric-furnace melting. The size and type of castings being made dictate the type of furnace. Foundries making small castings weighing from 1 to 500 pounds favor the electric process. Producers of large castings weighing from 500 pounds up to 25 tons or more use open-hearth furnaces.

Electric furnaces in foundries vary in size and the normal weight of charge runs from 250 pounds to 25 tons. Open-hearth furnaces in foundry practice usually have capacities between 10 tons and 100 tons. The present trend in melting equipment seems to be in favor of the electric process and many of the open-hearth foundries are converting to electric-furnace practice. The reason for this is the greater flexibility of the electric furnace over the open hearth, as well as various economic considerations.

In general, furnace charges consist of purchased scrap in the form of billets, shearings, flashings, punchings, plates and turnings; also, scrap from the foundry itself in the form of gates, heads, and scrapped castings. High-grade pig iron, low in phosphorus and sulphur, is used in the open-hearth furnace charges, and frequently in the electric-furnace charges when a high-carbon melt

is required. Ferroalloys and slag-making materials are used in about the same proportions in the melt as for steel-ingot production. However, the casting-from-melt yield is considerably lower than that generally experienced with ingots. For every ton of steel castings produced, at least three tons of raw materials are consumed, including scrap steel, pig iron, fuel oil, limestone, sand, organic and clay binders, and miscellaneous materials. This includes the mold-making materials.

Fifty per cent of the steel-casting tonnage is melted in open-hearth furnaces, approximately half being made in basic-lined furnaces. The basic furnace offers one distinct advantage in permitting partial removal of sulphur and phosphorus, thereby making possible the use of less costly scrap. However, in localities where scrap low in sulphur and phosphorus is abundant, the acid open-hearth process commonly is used for various reasons, some of which are largely a matter of beliefs. For example, it is claimed that acid open-hearth steel has less flakes and cooling cracks, and that it has fewer internal cracks or ruptures in heavy sections. Neither of these claims has been proved definitely. Records indicate, however, that less melting skill is required with the acid process, that refractory costs are lower, melting time is faster and that, in pouring castings, acid open-hearth steel has greater fluidity than basic open-hearth steel.

Much has been written concerning the operation of open-hearth furnaces, and elsewhere in this book the subject is treated in some detail. Suffice it to say that the melting process in foundry practice is very similar to that practiced in the steel mills, the chief difference being that greater amounts of deoxidizers are required in foundry practice to produce sound castings, free from porosity. It is necessary to add silicon and manganese in excess of 0.30 per cent and 0.60 per cent, respectively, for deoxidation purposes. Also, aluminum and alloys of calcium, manganese, silicon and zirconium commonly are added to insure complete deoxidation, removal of dissolved gases such as hydrogen and nitrogen, and, finally, for grain-size control.

Electric furnaces offer several distinct advantages over the open-hearth furnaces in the foundry. The modern arc furnace, with its top-charge mechanism, improved switchgear and automatic control, is an extremely flexible unit and rapidly is replacing the open-hearth furnace in the foundry. Electric furnaces permit a wider range of scrap selection than the open hearth, can be charged quickly and without the aid of a charging machine, operation requires fewer men, and the power costs are less than fuel costs in many localities. The furnaces can be shut down and allowed to cool to room temperature with less damage. The types of steels that can be produced in electric furnaces are unlimited. Highly-alloyed steels can be made as well as the plain carbon steels and electric furnaces are more flexible in the size and type of heats. This facilitates foundry planning and affects customer relations by the ability to make quicker deliveries.

Electric furnaces are lined with acid or basic refractories as available scrap or product characteristics may warrant. High-manganese steels are always melted in basic-lined furnaces because the slag from such steels is very destructive to acid refractories. Where low-sulphur and low-phosphorus scrap is not available, basic slags must be used to remove these elements, hence basic-lined furnaces are used. However, the major part of the electric-steel-casting tonnage is made by the acid-electric-furnace process.

The generally accepted method for making steel in acid electric furnaces is to melt hot, then by the applica-

tion of either iron ore or oxygen, bring the bath to a violent boil or "blow," following which the heat is tapped before the action subsides completely. The metal generally is deoxidized in the ladle by the addition of relatively large amounts of deoxidizers.

There is greater variation in the melting operation of basic furnaces than acid furnaces. However, the three principal methods employed in the basic furnace are: (1) the **dead-melt process**, in which a reducing slag is made up as quickly as possible and maintained throughout the heat; (2) the **double-slag process** in which the first oxidizing slag is removed and replaced with a white, lime finishing slag; and (3) the **single-slag method** with an oxidizing slag which may or may not be made reducing before tapping. Each method has its own specific advantages, depending upon the type of steel being made.

MOLDING FOR CASTING STEEL

Patterns and Molds for Steel Castings—The construction of the **pattern** is perhaps the most important single factor in the production of a casting. Not only must the pattern be dimensionally accurate, but full consideration must be given to making it meet the requirements of the foundry equipment and technique. The patterns for steel castings are usually made $\frac{3}{16}$ to $\frac{1}{4}$ of an inch per foot larger than the dimensions shown on the drawing to compensate for metal shrinkage, because steel castings cooling from the liquid state to room temperature contract approximately $\frac{1}{4}$ inch per foot, depending upon the chemical composition of the steel and the size and design of the casting. It follows, therefore, that to make dimensionally accurate castings provision must be made for metal shrinkage. Patternmakers make such adjustments by **shrink rules** or **patternmakers' rules** which are graduated to compensate for the necessary shrink allowance. Other details of pattern construction, such as allowance for **draft** to facilitate removal of the pattern from the molding sand, **padding** for feed purposes, avoidance of sharp changes in metal sections, and elimination of sharp edges, corners and reentrant angles, all require full consideration.

There are several types or classes of patterns, each fulfilling a specific need. Patterns may be made of wood or metal, as required, and used in conjunction with hand-molding or machine-molding methods, depending upon the number of castings to be made and the degree of precision required. Descriptions of patterns and molding machines and procedures will be found in the books listed at the end of this chapter.

The materials used for making molds vary to a great extent, not only from foundry to foundry, but within the same foundry. The size and type of castings, the composition and temperature of the metal, pouring methods and foundry technique, sand mixing and reclaiming facilities, and location of the foundry exercise a profound influence upon the type of molding material. Some foundries prefer to make molds of crude or **bank sand**. For special work calcined ganister or **Chamotte** is sometimes favored.

Patterns have been issued for many molding media, such as those used in the **Fischer process** (calcined aluminous-clay grog), or in the **Randupson process** (sand and cement). Highly refractory silica sands of known particle size, mixed with weighed or measured quantities of various types of clays, resins, dextrins, vegetable oils, and water to develop desired molding characteristics are used. **Plaster, plastic and wax patterns** have been used for special purposes, such as making an experimental casting. Wax patterns are used ex-

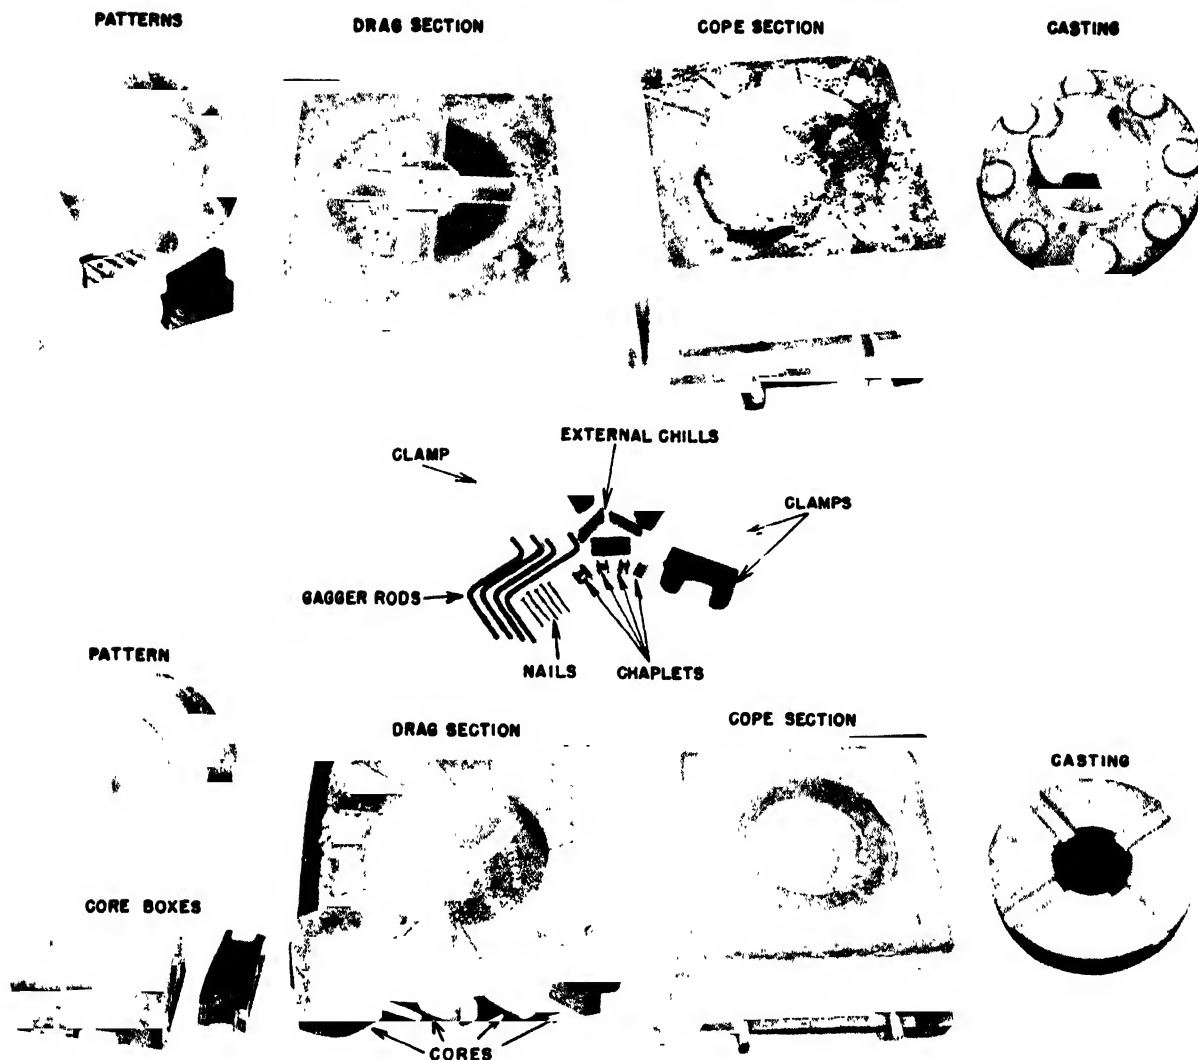

FIG. 18-1. Parts and accessories for preparing typical molds for two relatively small ferrous castings.

tensively for castings weighing a few ounces and a special operation known as the "lost wax" or "precision casting" process is based upon the use of such patterns; this process is described in more detail later in this chapter.

Other molding materials include **mold and core washes** which are sprayed, or swabbed, on the mold surfaces to make a smooth mold and resist metal penetration, **gaggers** or reinforcing rods which are placed around the pattern in the sand to add strength to the mold, and **chills** of various types are used to promote directional solidification and reduce the effect of severe temperature gradients caused by sharp changes in metal sections of the casting. **External chills** are placed directly on the pattern and the chill is flush with the mold wall when the pattern is removed from the sand. **Internal chills** are placed in the mold after the pattern has been removed. Internal chills are often more effective than external chills, but they must be positioned with the utmost discretion. **Chaplets** and stem anchors are used within the mold cavity to support an internal core. **Nails** frequently are inserted in the mold surface to prevent metal penetration and sand erosion. Rolled-steel,

cast-steel or wooden frames, commonly called **flasks**, are used to hold the molding sand around the pattern.

Flasks are made in two sections—the lower half is called the **drag** section; the upper half is called the **cope** section. Occasionally, there is need for a third section which is placed between the cope and the drag. This is known as the **cheek** section. The bottom of the flask is termed the **bottom board** or **bottom plate**. It is important that the cope and drag sections match properly. With small or medium flasks, this is accomplished by hardened pins placed on the outside of the drag section; with larger flasks, this matching is performed with guides, peep-sights, match blocks and many other ingenious devices. The flask sections and the bottom board are held together by "C" clamps and wooden or steel wedges. Figure 18-1 shows patterns, cope and drag sections of two different molds, and accessories required for one of the molds, and the finished castings produced with this equipment.

Making the Mold—The size and shape of the casting are the controlling factors in deciding how the molten steel should be introduced into the mold and where to locate gates, risers and vents. A flask is selected which

is sufficiently larger than the pattern to provide room between the pattern and the flask wall to accommodate at least several inches of sand and the gate system. The flask also must be sufficiently large to permit placement of the **feedheads** or **risers** which are attached to the pattern and leave spaces in the finished mold to serve as reservoirs for molten metal that supply extra metal to feed the voids formed by shrinkage as the metal cools and passes from the liquid to the solid state.

In preparing the mold for a typical steel casting of relatively small size, the bottom board or bottom plate is clamped securely to the flange of the drag section of the mold as shown in Figure 18—1. The pattern is set on the bottom plate in such a position that sand may be rammed over the top of the pattern. The amount of sand must be sufficient to prevent metal runoff, to develop the required strength to resist ferrostatic pressure, and to permit handling of the mold. **Facing sand** is riddled or sifted over the surface of the pattern to a depth of one inch and packed in any pockets and around the corners of the pattern. **Heap-sand**, which is nothing more than used facing and core sands, sometimes re-bonded, is rammed into the flask to a depth of four inches. Pneumatic air hammers may be used for this purpose, and many foundries use sandslingers. More heap-sand is added to a depth of six to eight inches, or until the flask is full and, after ramming, the excess sand is removed by a straight-edge. This operation is known as **striking off**. A bottom plate is clamped over the top of the flask and the entire flask section is rotated or turned 180°. The first bottom board is now removed and the cope section of the pattern is placed on the drag section. The two parts of the pattern are matched properly by dowel pins fitted into holes located in the face of the **parting line**, joint line, or split sections of the pattern. The cope section of the flask, which is reinforced with cross bars, is set on the drag section and fitted properly, as described. The cross bars in the cope section also serve to support gagger rods which reinforce the sand, thereby preventing possible distortion of the mold cavity by pressure of the metal entering the mold.

A finely ground sand, known as **parting sand**, is dusted on the face of the drag section to prevent cohesion of the sand in the cope section with the sand in the drag section. **Riser patterns** are placed at the desired locations on the casting pattern and a **sprue stick** or **gate tile** is placed upright on the sand surface of the drag near the point where the metal is to enter the mold cavity. Facing sand is then riddled over the pattern and packed firmly by hand. The gagger rods are placed and heap sand rammed into the flask in the same manner as described for the drag section. After ramming is complete, the riser patterns and sprue stick, if used, are removed. The cope section is removed from the drag and the cope and drag patterns **drawn** from the sand by **lifting screws**. Pneumatic vibrators are sometimes attached to the patterns for the purpose of freeing the pattern from the sand. The mold is smoothed off and patched, and rough corners and edges are rounded. The gate is cut in the drag section from the base of the sprue stick to the mold cavity. Cores, and chaplets, if required, are properly placed as shown by core prints and markings on the pattern. Provision for elimination of mold and core gases is made by jabbing a rod through the mold wall or by scratching vents across the drag section of the mold at the parting line. Internal chills, if required, are placed at this time. External chills are placed on the pattern surface prior to adding the facing sand.

If the casting is to be what is known as a **green sand casting**, the cope section of the mold is placed on the drag section and clamped securely to the bottom board.

A runner cup, a sand mold having an internal shape similar to a funnel, is placed directly over the gate, and the mold is ready to pour.

If the casting is to be what is known as a **dry sand casting**, the mold cavity is sprayed or swabbed with a mold wash, and placed in a mold oven before the cores are set. Operating temperatures of **mold drying ovens** vary from 300-800° F and the time of drying may vary from 4 hours to 72 hours, depending upon the type of molding sand, the size of the mold, and the drying characteristics of the oven. After drying, cores and chaplets, if required, are placed and asbestos rope or putty is placed on the joint surface for a seal. The cope section then is fitted properly on the drag section and, after placing the runner cup, the mold is ready to receive the molten metal.

Machine Molding—Fundamentally, machine molding methods differ little from the process previously described for the manual or floor molding operation, the chief difference being that the ramming of the sand and the removal of the pattern from the sand are performed by machine. Also, there are details of pattern construction, such as integral gates and, frequently, attached risers, which eliminate some of the work formerly done by hand. However, the placement of cores, patching and finishing of the mold still remain as the chief function of the molder.

A relatively new molding method known as "shell molding" lends itself to the production of molds by machine methods. This method of molding is described briefly in Section 2 of this chapter. It is especially adapted to production of large numbers of small repetitive castings.

Cored Molds for Hollow Castings—Many castings are designed with overhanging flanges, ribs, bolt holes, bosses and hollowed-out sections. Such castings, because of their irregular shape, cannot be produced simply by making a mold, and the foundryman must resort to the use of cores to meet the demands of the design. A core is nothing more than a solid shape made of sand. Sand is rammed either by hand or machine, or blown into a **core box**. When the core box is filled with sand and the excess sand "struck off" with a straight edge, it is turned over and the box lifted from the core thus formed. The ramming operation includes placement of reinforcing rods, or wire, for strengthening purposes. Vent rods are jabbed through the core to permit escape of gases. Sometimes wax wire is rammed in with the sand and, upon baking, the wax wire melts, thereby forming a passageway through which mold gases escape. As soon as the core is vented and sprayed with core wash, it is placed in an oven to bake. The baked core should be hard, strong, and smooth, but it should be sufficiently collapsible at high temperature in order not to cause the casting to "hot tear," i.e., pull apart due to contraction as the metal cools. Appendages attached to the molder's pattern permit the cores to be placed at the proper locations in the mold. These appendages are known as **coreprints** and have the same dimensions as the inside dimensions of the core box. The core prints are of sufficient length to provide a good bearing surface to support the core. It is sometimes necessary to tie the cores in the cope section of the mold or to use chaplets and stem anchors to provide additional support.

Cores are made by hand and by various types of molding machines, including sandlinger and rollover machines. For high production work, core blowers are used extensively. Core baking and drying operations require considerable attention and much use is being made of dielectric heating methods, as well as auto-

FIG. 18-2. Schematic vertical sections through various molds, illustrating types of gates frequently employed (After Briggs).

matically controlled oil- and gas-fired ovens. Perhaps one of the greatest problems in the foundry is the selection and development of core sands to fill the specific needs of the various types of castings. Such problems are so varied and of such importance that specialists are employed in many of the foundries to study sands and sand compositions.

Gates, Risers and Vents—The gate, as mentioned previously, is the channel or passageway through which the metal flows in filling the mold. The height, the cross-sectional area, and the shape of the gate, as well as the point at which it enters the mold cavity, are all important factors in any gate system. Many defects in steel castings, such as imbedded sand, cracks, shrinkage cavities, core failures, and misrun castings are attributed directly to poor gating practice. A gate, in order to function properly, must permit the flow of the metal into the mold with the least amount of turbulence. It must carry sufficient volume of metal with enough pressure to fill the mold quickly, and it must be arranged to permit proper distribution of temperature gradients.

There are four general types of gates, (1) the bottom gate, (2) the parting gate, (3) the top gate, and (4) the step gate which is a combination of the three aforementioned types. The bottom gate is used most commonly for large floor-molded castings. The parting gate is favored for smaller work and is used on practically all machine-molded castings. There are many modifications of each of the four types, such as horn gates, pencil or finger gates, swirl or whirl gates, skimmer gates, shower gates, ring gates and strainer gates. Figure 18-2 shows types frequently used.

There are two types of risers; (1) the open riser, and (2) the blind riser. Open risers are attached to the surface of the casting at some location on the cope side and extend through the sand to the surface of the mold. The size of the riser depends upon the size of the section to be fed and upon the design of the casting. In general, the cross section of the neck of the riser should be equal to the section thickness of the casting at the point of at-

FIG. 18-3. Schematic representation of an open or atmospheric type feedhead or riser (After Briggs).

tachment. The body of the riser should be slightly larger than the neck and the height at least 1.5 times its diameter or width (see Figure 18-3).

Blind risers usually are attached to the drag side of the casting and are covered completely with sand. The neck thickness should be $1\frac{1}{2}$ to 2 times the sectional thickness of the casting at the point of attachment. The diameter of the riser body should be 2 to $2\frac{1}{2}$ times the sectional thickness at the point of attachment. The height of the riser should be about 1.5 times the diameter and the topmost surface rounded off or dome shaped. In order to insure proper feeding action of blind risers, a sand core or carbon rod should be inserted in the top section. Also a vent or pop riser should extend from the top of the riser to the surface of the mold. The use of the core in blind risers is patented and is known as the

FIG. 18-4. Vertical section of a mold employing a Williams core in conjunction with a blind riser (After Briggs).

Williams method. The core serves to admit atmospheric pressure, thereby increasing feed efficiently. Figure 18-4 is a sketch of a Williams core on a blind riser.

Risers placed on steel castings present a serious problem to foundrymen from the standpoint of cleaning, because all risers must be removed prior to shipment. For this reason the Washburn core or necked-down riser is finding considerable use in conjunction with both open risers and blind risers. The necking core is nothing more than a core through which a small opening connects the riser to the casting. The thickness of the core and the size of the opening depend upon the size of the riser required. The necking core has the advantage that risers can be removed easily by sledge hammers, whereas oxyacetylene torches are necessary to remove conventional risers. Figure 18-5 illustrates use of a necking core with a blind riser.

FIG. 18-5. Washburn necking core used to neck down the riser to facilitate removal, applied to a blind riser using a Williams core. (After Briggs).

During the teeming process many mold gases are formed by volatilization and burning of sand binders and by the expansion of the cool air within the mold cavity. Provision for the exhaust of such gases is made by jabbing wires through the mold to the surface or by the use of very small risers. The small holes thus formed are called vents and usually are located over points of the mold cavity where trapped gas might be expected, such as pockets and high points, or at flanges where a blind riser is used in place of an open riser. The vent rod preferably should be flat in shape rather than round. Some foundrymen contend that the practice of venting is unnecessary and results in excessive cleaning costs. However, the practice still is carried on in most foundries.

STEEL CASTING AND FINISHING OPERATIONS

Casting—There are two classes of castings, static castings, and centrifugal castings. The discussion, so far, has dealt only with static castings, i.e., castings which depend upon proper molding practice, atmospheric

pressure and gravity to form castings free from internal shrinkage cavities and other defects. The second class, centrifugal castings, as the name implies, makes use of centrifugal action to perform the function of gravity in static casting. There are two types of centrifugal castings—the horizontal type and the vertical type. In the horizontal type, the mold rotates on a horizontal axis. This method is used principally for making long, concentric, hollow castings with uniform wall thickness, where risers are not required. Tubing, pipe, gun barrels, bushings, sleeves, etc., are typical castings made by this process. The vertical method, employing rotation about a vertical axis, is essentially a pressure-casting method and depends, in part at least, on gravity, atmospheric pressure, and proper location of riser or risers to produce sound castings. Gears, piston rings, impellers, propellers, turbine diaphragms, etc., with sections too thin to be cast by static methods or where exceptional feeding problems arise which cannot be surmounted in any other way, are made by the vertical centrifugal process. There are several advantages to be gained from centrifugal casting methods: (1) castings are said to be sounder and have fewer inclusions, (2) fewer cleaning problems, and (3) a 10 to 30 per cent increase in yield.

Shaking Out, Cleaning, Finishing and Testing—After the castings have been poured and sufficient time allowed for solidification and cooling, they are shaken out, i.e., the castings are removed from the flask and sand. This operation is performed by placing the entire flask on a vibrating grid called a shakeout machine. The clamps are removed from the flask sections and the vibration of the machine causes the sand to fall loose and free of the castings. The castings are then removed to the cleaning room where they are subjected to blast cleaning or put through a tumbling barrel, where the abrasive action of sand particles or metallic shot impinging upon the walls of the castings loosens and removes adhering sand. Risers and gates are removed by oxyacetylene torch, electric arc, abrasive or friction saws, or by sledge hammers. Fins and surface defects found during preliminary inspection are removed as far as possible by chipping and burning. Within recent years, the powder-injection acetylene torch has been applied successfully to the removal of burnt-on sand. The riser necks, gate stubs, and slight surface imperfections are dressed by grinding wheels of various types and sizes. Repairs by welding also are performed sometimes, depending upon the carbon and alloy content of the steel. Castings containing more than 0.30 per cent carbon or of equivalent hardness that require repairing by welding are welded prior to heat treatment. After heat treatment, the castings are subjected to final surface-finishing operations—chipping, grinding, or sand blasting—as required. Finally, they are inspected for surface defects and dimensional accuracy. This inspection may include examinations utilizing X-ray, gamma-ray, magnetic-particle, fluorescent-penetrant, or ultrasonic methods.

HEAT TREATMENT OF STEEL CASTINGS

In the "as cast" or "green" state, steel castings are relatively brittle and possess poor mechanical properties. It follows, therefore, that in order to render them serviceable they must be subjected to a heat treatment which will refine the grain and break up the dendritic structure, relieve internal stresses, and develop the desired physical and mechanical properties. The heat treatment applied to steel castings depends upon the chemical composition, section size, design, grain size,

and the desired mechanical properties. Because of the variations in size, section and design of castings, their heat treatment requires considerable care. However, steel castings respond to heat treatment similarly to wrought steel products and, for all practical purposes, the same rules apply, with care being exercised in placing castings in the furnace in such a way that there is minimum of danger of warpage, distortion or cracks which may cause them to be unfit for service. The common heat treatments applied to steel castings are as follows:

Annealing—The castings are placed in a furnace and heated slowly to a temperature slightly above the A_c point, usually 1650°F for carbon steels. The castings are held at that temperature 1 hour per inch of thickness of the heaviest section and cooled slowly in the furnace. Such treatment relieves casting stresses, refines the grain, and serves to eliminate the dendritic structure. Annealing raises the tensile and yield strength and increases ductility. It also improves machinability, especially of high-carbon steels.

Normalizing—The normalizing treatment is similar to the annealing process, except that the castings are removed from the furnace at the end of the soaking or holding time and allowed to cool in still air. The normalizing treatment produces a harder steel with higher yield and tensile strength than the annealed product, with ductility value approximately the same. However, internal stresses are not removed to the same extent as in the annealing process. Double normalizing is often employed to produce a more uniform grain structure and such treatment improves the ductility. To remove internal stresses or to reduce the hardness of normalized steels, a draw or tempering treatment is used frequently, i.e., heating the casting to a temperature below the critical range and allowing it to cool in the furnace. Tempering temperatures for steel castings range from 500 to 1250°F .

Quenching and Tempering—The quenching and tempering treatment is confined principally to high-carbon and alloy-steel castings where high strength and resistance to impact and/or abrasion is required. The general practice is to anneal or normalize the castings, reheat and quench. The tempering treatment should follow immediately, because internal stresses set up by the quench may cause the castings to crack. Sometimes, it is necessary to use a time quench to eliminate cracking, in which case the casting is immersed in the quenching bath for a predetermined time interval, removed, and subjected to the tempering treatment immediately. Such procedure must be controlled closely; otherwise, wide variations in hardness values may result. The end-quench hardenability test is of great value in determining quenching and tempering procedure for steel castings.

Some alloy steels, particularly straight manganese steel in the range of 1.00 per cent up to 2.00 per cent, are susceptible to temper brittleness. Such steels have low impact and ductility values when cooled slowly from the tempering temperature. To avoid this, it is sometimes necessary to cool quickly from the tempering temperature by quenching or air cooling.

Flame Hardening—It is sometimes desirable that castings be differentially hardened, i.e., parts of the casting subject to extreme wear or abrasion should be harder than another part of the same casting which requires a machining operation. A pinion gear, for example, should have hard, wear-resistant teeth with a machinable bore. In such cases, the castings first are annealed or normalized and then only the surfaces to be hardened are heated to the hardening temperature by

a torch or induction-heating apparatus. The heated parts are quenched in water. A time quench often is employed to prevent critical internal stresses. Sections can be hardened up to $\frac{1}{4}$ inch in depth by the flame hardening process.

HEAT- AND CORROSION-RESISTANT STEEL CASTINGS

Highly Alloyed Steels—Normally, high-alloy steel castings contain at least 12.0 per cent of alloying elements, such as chromium, nickel, cobalt, copper, molybdenum and tungsten, although 4 to 6 per cent chromium steel is generally considered in this class. Various alloy combinations have been developed by consumers and manufacturers for specific applications where conditions of heat and corrosion are critical. There is no clear line of demarcation between heat-resistant castings and corrosion-resistant castings since corrosive media, in the form of fumes and exhaust vapors, usually accompany high temperatures. Moreover, the so-called stainless or corrosion-resistant castings possess excellent mechanical properties at high temperatures. It is not uncommon, therefore, to see castings of a composition designed to resist corrosion being used for heat-resistant applications, and vice versa.

Typical Applications—Heat- and corrosion-resistant castings serve a very broad field. Mine pumps, impellers, fans, valves, valve trim, tubing, sleeve nuts, return bends, agitators, retorts, stills, vessels, digesters, thimbles, nozzles, and centrifuges, are but a few of the castings being used in chemical plants for corrosive applications. The explosives manufacturers, oil and petroleum refineries, paper mill plants, nylon and fabric manufacturers, food and medicinal producers, and the mining and ore-concentrating industries use many corrosion-resistant castings. Heat-resisting alloy castings are used in practically every installation where temperatures exceed 1200°F or where alternate heating and cooling cycles are employed; typical examples are chain conveyors, blower tubes, carburizing trays, recuperators, heat exchangers, hearth plates, grate bars, dampers, retorts, rolls, furnace doors, skid bars, carrier blades, muffles, safety sleeves, fractionating towers, normalizing shafts, guides, piercer points, and tube supports.

In the past, the optimum chemical compositions were determined largely by trial and error methods, but in recent years scientific studies and tests conducted by the Alloy Casting Institute and other interested parties have done much toward the standardization and proper use of the various grades of high-alloy steels. Table 18—II shows the compositions of some of the important grades of heat- and corrosion-resistant steels used for castings.

Melting—Steels for heat- and corrosion-resistant castings are melted in arc-type electric furnaces and high-frequency electric induction furnaces. The direct-arc electric furnace is used more extensively, but modern developments in induction melting equipment make it an extremely desirable unit for melting alloy steels for metallurgical, as well as operating, reasons. Furnace linings may be acid or basic and, in the case of the induction furnace, the lining may be neutral. The basic-lined furnace has the advantage of greater alloy efficiency and makes possible the use of chrome ore and nickel oxide for chromium and nickel additions. Also, it is possible to oxidize and reduce heats containing alloy scrap without serious loss of expensive alloys. On the other hand, acid furnaces require less skill to operate, they are faster, and the refractory costs are lower. Melting costs of induction furnaces compare

(a) For free-machining properties, suitable combinations of Se, P, Mo and S may be used.

(b) Silicon content varies for different proprietary alloys.

favorably with acid- or basic-lined arc furnaces, and chemical composition and metal temperatures can be controlled within closer limits. Moreover, alloy recoveries are said to be higher. The induction furnace is limited to the dead-melt process but with present developments in flushing inert gases, such as argon and nitrogen, through the bath to remove dissolved gases, this does not pose a serious disadvantage.

Regardless of the type of melting unit, strict metallurgical control is necessary to produce high-alloy steels. Care must be exercised in the purchase of ferroalloys and other raw materials, and scrap must be segregated according to composition and used with utmost discretion. Because most furnaces used for melting alloy steels for foundry use are small, seldom exceeding three tons' capacity, heats are made rapidly and time is not available to run control analyses. For this reason, complete control of furnace operation and all raw materials and scrap is necessary.

Casting—High-alloy castings are made in static molds and centrifugal molds of the horizontal or vertical type. By far the greater tonnage is produced in static molds by conventional molding methods. However, a large number of horizontal centrifugal castings are made in the form of tubing, retorts, rolls and rollers. For work of this type, the centrifugal method is of great advantage since casting yield approaches 90 per cent, no cores are required, and the molds may be made of sand or, in some instances, cast iron sprayed with a highly refractory material. The vertical centrifugal method of casting is used only when static methods fail and the castings cannot be made any other way. Impellers containing thin vanes, for example, or castings designed in such a manner that they cannot be properly fed, are made by the vertical centrifugal method.

Molding—Fundamentally, the molding procedure for high-alloy castings is the same as that employed for carbon-steel castings. However, greater skill and more

precision is required on the part of the molder because excess stock on castings necessitates expensive machining operations. Every effort must be expended to produce clean, smooth, sound castings. The molding sand must be rigidly controlled and the particle size and bonding must be such that details of the pattern are reproduced accurately. The risers and gates should be located so as to avoid internal defects and center-line shrinkage, for such defects in castings exposed to high temperatures or corrosive media cause premature failures. The use of internal chills should be avoided, but if the casting problem cannot be surmounted in any other way, the chill material should be of the same chemical composition as the metal in the casting. Likewise, stem anchors and chaplets should be used sparingly and with care. Chill nails should never be used on high-alloy castings because contamination of the surface of the casting by the steel nail head may initiate corrosion and ultimately cause failure.

Finishing Operations—Cleaning and finishing operations for high-alloy steel castings differ but slightly from ordinary steel castings. Shot blasts or other abrasive cleaning devices must contain high-alloy shot or what is called high-alloy sand, since steel shot causes the castings to corrode. Risers and gates are removed by burning with an electric arc, although abrasive or friction saws are sometimes used for this purpose. The riser and gate pads are removed completely by grinding and all surface imperfections must be smoothed off by grinding. Frequently, alloy castings are ground to template. Casting repair by welding is limited strictly to minor defects and when welding is permitted, a rod of the same chemical composition as the casting generally is used. Heat treatments vary according to compositions, and range from carbide-solution treatments for corrosion-resistant castings such as 18 Cr-8 Ni, to precipitation-hardening treatments for the high-chromium, low-nickel-molybdenum steels. Steels containing 11.5 to 14.0 per cent chromium respond to the conventional hardening and tempering treatments.

Heat-resistant alloys, such as 24 Cr-12 Ni, are sometimes treated to improve machinability, in which case they are heated to approximately 1600° F and slowly cooled. The purpose of the treatment is to precipitate carbides.

Before shipment, castings are checked thoroughly for dimensional inaccuracies and surface imperfections and finally are cleaned in a sand blast or similar equipment.

Methods of Sampling and Testing—Sampling and preparation of samples for chemical tests have become standardized fairly well in all foundries. In general, test specimens for chemical analyses are poured from the ladle at about the mid-point of the teeming operation so that the sample is representative of the entire heat. The sample is cleaned and drilled; the first ¼ inch of drillings is thrown away as insurance against contamination. The chemical composition is then determined from subsequent drillings according to proven analytical procedures. Heat numbers are stamped on the castings and test specimens, thereby making possible the identification of the chemical composition of the castings. Most foundry laboratories are equipped to determine completely and accurately the compositions of steels, ferroalloys, sands, and various raw materials.

Mechanical properties of cast steels are determined from test coupons or test lugs cast integrally with the castings. At times it is necessary, by reason of the size or design of the casting, to make separate test coupons which are identified properly with the castings they represent by heat numbers stamped on the castings and coupons. The test bars always are heat treated with the castings, machined and tested in accordance with standard mechanical-testing procedure. Test specimens cut from castings sometimes show inferior mechanical properties when compared to standard coupon specimens. This is due principally to the mass effect, although in some instances it may be attributed to improper foundry technique, such as inadequate feeding action. Generally, results of mechanical tests as performed in the foundries may be considered indicative of the quality of the cast-

FIG. 18-6. Typical products produced by the lost wax or investment molding process for precision casting of materials not readily machinable that cannot be formed by hot or cold working. (Courtesy, Westinghouse Electric Corporation.)

ings, but it should be recognized that excellent mechanical properties shown by tests do not preclude the possibility of poor mechanical properties in a casting.

Many foundries make use of modern non-destructive testing equipment, such as X-ray and gamma-ray apparatus. Also, an ultrasonic method for detecting internal defects and magnetic particle testing for detecting surface imperfections, such as cracks and small sand inclusions, is used extensively. In the case of high-alloy steels of the austenitic type which are non-magnetic, a method which makes use of a fluorescent penetrant and black light, is used to indicate cracks. Destructive tests in which castings are machined to complete destruction are employed frequently to determine the internal soundness of castings. Such tests are used as control measures and serve to establish foundry technique for subsequent castings. The microscope has been used in foundries for many years as a control tool to establish heat-treating practices and for other related metallurgical investigations.

PRECISION STEEL CASTINGS

The lost wax or investment molding process of making castings is often referred to as "precision casting." Castings weighing one pound or less can be made to tolerances of 0.005 to 0.010 inch. Larger castings weigh-

ing as much as 10 pounds have been made successfully by this method. The process is restricted largely to high-alloy steel parts which cannot be machined readily and which cannot be formed by hot or cold working methods. Such parts include valve parts; turbine blades, buckets and nozzles; molds and dies for the plastic and ceramic industries; small gears for timers; hobs, milling cutters, magnets, jewelry, surgical and dental tools, etc. Figure 18-6 shows some typical precision castings.

The process consists of making a pattern of free-machining steel, around which a mold is formed of an alloy of low melting point. The mold thus formed is used for making wax patterns. The wax patterns are then used to make up molds similar to those used in the conventional molding process, except that risers are not required and the molding sand is bonded with an ethyl silicate, making a very hard and highly refractory mold when dried. The wax patterns within the mold are not lifted out of the sand but are removed by melting with steam or hot air; hence, the name "lost wax." The molds then are inverted over small induction furnaces containing the metal to be cast and clamped to the furnace. The furnace is rotated 180 degrees and the molten metal forced into the molds by air pressure, by centrifugal force, or by vacuum. The castings finally are cleaned and finished just as in conventional casting practice.

SECTION 2

IRON CASTINGS

Pig Iron for Castings—Castings are of innumerable kinds and uses, roughly grouped as **chilled-iron castings**, **gray-iron castings**, **alloyed-iron castings**, **malleable castings** and **nodular-iron castings**. In general, castings are made by mixing and melting together different grades of pig iron; different grades of pig iron and foundry scrap; different grades of pig iron, foundry scrap and steel scrap; or different grades of pig iron, foundry scrap, steel scrap and ferroalloys or other metals. In rare instances, molten iron direct from the blast furnace is run to a mixer, then to an electric furnace in which its composition is adjusted. In all remelting operations, the pig iron undergoes some change. Hence, physical properties of the pig iron itself are held subordinate to chemical composition in iron for remelting. However, by selecting iron of different grades and controlling the rate of cooling, the widest variations in mechanical properties may be obtained, from extreme hardness and brittleness with low impact resistance to extreme softness with, however, considerable strength and enhanced toughness. Thus, without the use of alloys and by selecting different malleable and foundry pig irons and controlling the rate of cooling, the following ranges in properties may be obtained:

Brinell Hardness Number	100 to 500
Tensile Strength (Lbs. per sq. in.)	10,000 to 60,000
Deflection (Transverse, in.)	0.04 to 0.36
Modulus of Elasticity (Lbs. per sq. in.)	12,000,000 to 29,000,000

Besides these properties, representing hardness, strength and elasticity, other important properties in iron for castings are listed as follows:

a. **Fluidity**, at time of casting, which depends upon composition and temperature. The melting and freezing points of pig iron and cast irons of eutectic and

hypoeutectic composition, for a given phosphorus content, vary inversely with the carbon and silicon, from 1990° F (1088° C) with 4.40 per cent carbon and 0.6 per cent silicon to 2280° F (1250° C) with 3.56 per cent carbon and 2.40 per cent silicon, the melting point varying inversely with the combined carbon for a given low (under one per cent) silicon content.

b. **Shrinkage**, which is the net result of contractions and expansions in cooling to atmospheric temperature, i.e., through the point where solidification begins, through the solidification range, and in cooling from this range to atmospheric temperature. Shrinkage depends upon the temperature of the iron as it enters the mold, the composition of the iron, the rate of cooling, and subsequent heat treatments. and it varies from $\frac{1}{32}$ to $\frac{1}{8}$ in. per ft.

The net volume change on cooling from the liquid state is incurred stepwise and is complicated by structural and other changes that take place, somewhat in the following sequence and at the indicated approximate temperatures.

1. Contraction in the liquid state—Tapping temperature to solidification (say 2200° F, corresponding to 1205° C).
2. Contraction, liquid-to-solid, solidification—Temperature nearly constant at freezing, largest change.
3. Contraction of austenite and ledeburite—2200° F (1205° C) to 2050° F (1120° C).
4. Expansion due to graphitization—2050° F (1120° C) to 1950° F (1065° C)—large.
5. Contraction due to cooling—1950° F (1065° C) to 1325° F (720° C).
6. Expansion—austenite to pearlite, gamma to alpha iron—1325° F (720° C).
7. Contraction due to cooling—1325° F (720° C) to room temperature.

- c. **Growth** is the tendency of castings to increase in volume after repeated heatings to temperatures between 850 and 1650° F, (455 and 900° C) in the absence of stress. It is usually measured in linear units and expressed in per cent. It varies from essentially zero to several per cent (there is an example of a reported extreme of 50 per cent) according to the time of heating or number of heating cycles and type of iron. For ordinary castings, 5 per cent is extreme, while a growth of 0.002 inch per linear inch is common, and depends upon composition and prior heat treatment. The causes of growth are believed to be (1) graphitization and (2) penetration of active gases into the discontinuities of the coarser-grained irons.
- d. **Creep** is the tendency to increase in length under stress (tension) at elevated temperatures above 700° F; the stress being but a fraction of that required to break a specimen of the material in a short-time tension test at room temperature. As it is expressed in different ways, one example is cited for an ordinary gray iron. In short-time tension tests, the breaking loads were 34,200 lb. per sq. in. at 70° F, and 35,100 lb. per sq. in. at 700° F; at a testing temperature of 700° F the test broke in 9 days under a load of 18,000 lb. per sq. in., and in 90 days under a load of 9,000 lb. per sq. in. Creep is lessened by certain alloy additions.
- e. **Porosity, density, and closeness of grain** are designations referring primarily to macroscopic structure, particularly of heavier sections, as revealed by fractured surfaces. A porous structure is conducive to weakness, and is indicative of a condition bordering on unsoundness, which term is applied when the structure shows more clearly visible blowholes or gas pockets, or small cavities due to bleeding or shrinkage. The term "density" is sometimes used loosely to designate grain size rather than mass per unit weight; thus, iron showing a fine-grained fracture is said to be a "dense" iron. Porosity may be due to segregation of low-melting constituents, to minute slaglike inclusions, or oxides that react with carbon to form gas while the casting is solidifying.
- f. **Machinability** (the capability of being machined) may be viewed from various standpoints. Most frequently it is considered to be the characteristic (of the metal being machined) which causes more or less wear on the cutting tool; less frequently the definition involves the power required for the machining operation; often it refers to the degree of smoothness obtainable on the machined surface. With due precautions to keep the casting free of sand or dirt, machinability is controlled through the composition and rate of cooling, but often must be sacrificed for some more essential property, such as strength or toughness.
- g. **Graphitization**, a phenomenon common to pig iron and cast iron, refers to the decomposition of iron carbide or, in any event, the rejection of elemental carbon in a casting after solidification has taken place, the carbon being liberated in the form of graphite which is usually found existing as minute, flaky particles disseminated throughout the casting. This property is controlled basically through composition of the iron, and is very important in castings, particularly malleable castings in which, upon reheating, carbon is rejected as nodules. As will be shown later, the formation of graphite is promoted by slow cooling, hindered or prevented by rapid cooling, and, if suppressed, can be brought about by subsequent heat treatment.

The effects of the different elements upon the properties of pig iron and cast iron will now be discussed.

IRON COMPOSITION vs. PROPERTIES

Forms of Carbon in Pig Iron—The factors influencing the carbon content of pig iron were discussed in Chapter 12. In considering the effect of temperature on molten iron, it is necessary to keep in mind that the effective temperatures are inevitably above a certain minimum of about 2085° F (1140° C), marking the freezing point of the iron-carbon eutectic. Referring to the iron-carbon diagram (see Index) and Figure 18-7, it will be observed that iron at 2370° F (1300° C) may absorb about 5.0 per cent carbon. Being a saturated solution, cementite (Fe_3C , 93.33 per cent Fe and 6.67 per cent C) crystallizes and separates as the liquid cools to 2065° to 2085° F (1130° to 1140° C), at which temperature we have the eutectic (lowest freezing) liquid, called ledeburite, containing 4.3 per cent carbon. Upon freezing, this eutectic liquid becomes a two-phase solid, one phase of which is composed of primary austenite (47.7 per cent) containing 1.7 per cent carbon in solution (equivalent to 12.1 per cent Fe_3C) and the other (52.3 per cent) of cementite. In the freezing of the eutectic, no drop in temperature occurs until heat equivalent to the heat of fusion of this eutectic is abstracted. Then, if the cooling is extremely rapid, practically all the carbon remains in these combined forms and the metal is extremely hard and brittle. But the saturated liquid solution may, in rapid cooling, produce a supersaturated solid solution. As another complication, the iron changes its allotropic form at about 1310° F (710° C) losing its power to hold carbon in solution, and if then the cooling is slow, some of the already formed cementite breaks down, or decomposes, to precipitate free carbon, which assumes the graphitic form, and usually is distributed as tiny flakes throughout the metal. The remainder of the carbon remains as combined carbon, part of which may be present as free or "proeutectoid" cementite, and some as pearlite, a fine lamellar aggregate of iron and cementite (so-called from its resemblance to mother-of-pearl). This last component is a microscopically laminated structure composed of alternate layers of nearly pure iron, called ferrite, and cementite, in the proportion of about 7 parts ferrite to 1 part cementite (about 0.80 per cent carbon). The proportion is by no means constant. The presence of pearlite in cast iron usually strengthens it without producing too great an embrittling effect.

Influence of Silicon—The silicon content of the iron is second only to its carbon content in regard to its effectiveness as a means for controlling the properties of the castings. As it is increased above 3.5 per cent, it makes the iron matrix more and more brittle, forming silvery iron, so that it is generally held to amounts between 0.5 and 3.0 per cent. Since it tends to throw carbon out of solution, as explained in the discussion of carbon in pig iron in Chapter 12, it is used as a "softener" in gray-iron castings, as a graphitizing agent in malleable castings or castings to be heat treated, and to regulate depth of chill in chill castings. With sulphur under 0.05 per cent, even one per cent silicon makes it difficult to obtain a chill, (an external zone of hard cementitic iron without appreciable graphite). Below one per cent, the chilling properties are roughly inversely proportional to the silicon present. Its effect in increasing the rate of graphitizing the combined carbon in white iron for malleable castings is remarkable. In a certain casting, for example, raising the silicon from 0.7 per cent to 1.0 per cent shortens the annealing cycle

FIG. 18-7. Photomicrographs of typical microstructural constituents of cast iron as influenced by heat treatment and cooling rate. Sample 1: annealed specimen, showing graphite flakes in a fine pearlite matrix. Sample 2: "Chilled" sample showing ledeburite containing long needles and irregularly shaped areas of iron carbide (cementite; Fe_3C). Sample 3: Annealed specimen; region near chilled surface, showing areas of "chilled" ledeburite and graphite in a fine pearlite matrix. Sample 4: Annealed specimen; showing ledeburite and graphite flakes in a fine pearlite matrix. White constituent is cementite. All samples etched with picral. Magnifications: Samples 1, 2 and 3, $100\times$; Sample 4, $1000\times$.

from 180 hours to 72 hours. Silicon above 2 per cent hardens the matrix of iron solid solution to such an extent that machinability is adversely affected. Silicon added to white iron until it just turns gray increases the toughness by changing massive Fe_3C to pearlite and graphite, but more weakens it by forcing the pearlite ratio below 0.80 per cent carbon and increasing the graphite. Silicon tends to decrease shrinkage, to prevent blowholes, but increases the tendency to growth; silicon is oxidized in the cupola or air furnace and excessive amounts thus may favor a dirty casting, due to the entrapment of silicate-type inclusions. Silicon, from 1.5 up to 4.5 per cent, increases the resistance of the iron to atmospheric and acid corrosion, and more than 10 per cent greatly protects the metal from all forms of oxidation and from chemical attack.

Effects of Manganese—As to whether high manganese content has an overall good or a bad effect on cast iron, there is much difference of opinion, some considering it almost as a cure for all troubles and others condemning it as a source of much trouble, especially in chilled castings. While it tends to hold carbon in solution, iron in which chill is produced by increasing the manganese content alone is "soft" and tends to spall. In moderate amounts, it is said to prevent cracking of

the surface and also spalling to some extent, especially in chilled rolls, and it may harden the chill, if other conditions are right. It does tend to decrease blowholes, increase fluidity, and to neutralize the effect of the sulphur present. The amount used in castings varies from 0.1 to 2.0 per cent, 0.5 to 0.7 per cent being most common. In malleable castings, it is added in proportion to the sulphur, and according to the formula, $\text{Mn} = 2\text{S} + 0.15$. Held to these proportions, it will be found ultimately as MnS and in the cementite, and will not prevent graphitization of the cementite while larger amounts of manganese tend to stabilize cementite and increase growth. In high-grade gray-iron castings, the per cent manganese is held between 5 and 7 times the sulphur.

Influence of Sulphur—Sulphur in pig iron is considered now to be less injurious than was thought formerly. As sulphur, except for special purposes (e.g., enhanced machinability), is undesirable in steel, and as the blast furnace affords the only positive and economical means of reducing it, pig iron containing less than 0.05 per cent is preferable for making steel by all the fusion processes. In castings, it is varied from about 0.04 per cent to 0.20 per cent, though in irons for foundries it will seldom exceed 0.1 per cent. Iron melted in

cupolas always takes on sulphur from the coke, the percentage sometimes being doubled. Sulphur with iron forms sulphide, which is soluble in the liquid metal and has a melting point that is lower than the other constituents of the iron. This sulphide in iron used for castings has a three-fold influence. First, it tends to hold the carbon in combined condition, hence, can be used to increase the depth of chill in chilled castings, but in malleable castings and other castings that are to be heat treated, it thus retards graphitization, if it is not fully neutralized with manganese, and may be very undesirable. Chill produced with sulphur may be very brittle; low-silicon iron containing between 0.2 and 0.4 per cent sulphur often cracks when cooled rapidly. Second, its low melting point causes it to segregate as the iron solidifies, thereby causing the condition in castings known as bleeding. Third, it increases the shrinkage of the iron to a marked degree, thus increasing the difficulty of making accurate castings and increasing the tendency to form cracks, which are a result of the high shrinkage.

Influence of Phosphorus—Since compounds of phosphorus present in the materials charged into the blast furnace are completely reduced, all the phosphorus in the raw materials is ultimately found in the metal. Therefore, its content must be regulated by proper selection of raw materials. High phosphorus content causes a slight brittleness in pig iron and markedly reduces the total carbon content. Ferrophosphorus containing about 24 per cent phosphorus is almost carbonless and melts between 2245 and 2310° F (1230 and 1265° C). The melting point range for the 17 to 19 per cent grade is 2426 to 2498° F (1330 to 1370° C). Lesser amounts permit a proportionate increase of carbon, so that the total carbon in an iron containing 0.20 per cent phosphorus may be as high as 4.25 per cent. In this respect its action is not selective, since the ratio of combined to graphitic carbon is not affected. Phosphorus is known to form a compound, Fe_3P , with iron, containing 15.6 per cent phosphorus, but it apparently is able to combine or alloy with it in any proportion up to 25 per cent.

In pig iron and cast iron, Stead found that phosphorus forms a ternary eutectic solution containing 91.19 per cent iron, 6.89 per cent phosphorus, and 1.92 per cent carbon, to which Sauveur has given the name steadite. The amount formed in pig iron depends upon the phosphorus present, and since steadite has a low fusion point, the influence of phosphorus is to lower the freezing range of the iron. Another effect is to decrease the pearlite, so that more than one per cent phosphorus decreases the strength of the casting rapidly, the maximum strength being obtained with 0.25 to 0.40 per cent. For uniformly thin castings, such as stove plate and sanitary ware that is to be enameled, from 0.55 to 0.75 per cent is used with marked benefit to obtain the necessary fluidity and good mechanical properties. But in castings with thin and thick parts, such as engine blocks, these percentages of phosphorus make the thick portions porous, so that not more than 0.30 per cent can be permitted. High phosphorus also increases the shrinkage, particularly of the heavier parts, and increases the harmful stress-producing shrinkage (called "draw" shrinkage) and those making highest type castings generally agree that phosphorus above 0.30 per cent tends to produce unsound, porous, and brittle castings. Since the required fluidity can be had by raising the temperature, better results are obtained by lowering the phosphorus to 0.12 to 0.20 per cent and increasing the temperature. Castings thus made have a closer grain and machine better than those made with higher phosphorus content.

Therefore, this range is recommended as the best for general work, including machinery castings of various kinds. In general, the resistance of unalloyed cast iron to corrosion decreases as the phosphorus content is increased above 0.05 per cent.

Effects of Chromium—Chromium occurs only occasionally, and in traces, in pig iron made from ordinary iron ore, but it now is added commonly to iron for high-grade castings in amounts from 0.1 to 3.5 per cent. It is a carbide-forming element, hence it holds the carbon in the combined state, opposes graphitization, decreases the tendency for growth, and increases the hardness of the matrix. In moderate amounts of 0.1 to 0.5 per cent, it increases the strength, but greater additions are made with some increase of brittleness. In high-grade castings, it is used mainly to increase the resistance to wear. It is used also with other elements, particularly nickel and copper, to obtain resistance to corrosion and growth. Additions of chromium are made to the iron in the ladle, as solid or preferably molten ferrochromium. Its effects were early studied and reported by Hadfield in 1892 (see: Iron and Steel Institute, Vol. II, 1892).

Influence of Nickel—Nickel, like chromium, is rare in pig iron made from ordinary iron ores; but its use in high-grade castings is common, the amount added to gray-iron castings varying from 0.10 to 2.50 per cent, and to special alloy castings from 5 to 15 per cent. Nickel dissolves in the iron, and, like silicon, promotes graphitization; but, unlike silicon, it does not graphitize eutectoid cementite (that is, the portion of cementite that goes to make up pearlite) and it causes a reduction in the size of the graphite plates, giving a "closer grain." Therefore, in the smaller percentages, it is added to toughen the iron, prevent formation of massive carbides, and increase machinability. For example, one per cent added to gray iron, with carbon reduced from 3.50 to 3.00 per cent and silicon from 1.50 to 1.00 per cent, doubles the tensile strength and increases the Brinell hardness from 175 to 225, and gives an iron that is readily machinable. From 5 to 6 per cent nickel hardens the iron and may result in a martensitic matrix, the Brinell hardness being 250 to 280. A maximum of about 360 Brinell is obtained with 10 to 12 per cent nickel; while larger amounts, about 12 to 16 per cent, produce a distinct type wholly austenitic (except for cementite or graphite) and much softer, the Brinell hardness being as low as 130 with 18 per cent nickel. In these larger amounts, it is used in conjunction with chromium, with copper and chromium, or with silicon and chromium, to produce various special corrosion- and heat-resistant irons. In cupola practice, nickel is added in the form of shot to the metal in the ladle; in air- or electric-furnace practice, it may be added as pig nickel to the charge in the furnace, or in the form of shot in the ladle. Commercial forms of nickel used for this purpose contain some carbon, which should be considered if it is added in large amounts.

Influence of Copper—Copper may occur in pig iron, if it is present in the charge. Usually, it is absent. It is added to castings in various proportions from 0.10 to 2.00 per cent in gray-iron castings and up to 7.00 per cent in special alloy-iron castings. In the smaller amounts, its effects are similar to nickel, decreasing slightly the combined carbon, increasing the strength, preventing formation of massive carbides, improving machinability, and in addition, increasing the fluidity and decreasing the shrinkage slightly. Its solubility in iron is limited, but is increased by nickel, in conjunction with which it is used up to 6.5 to 7.0 per cent to produce corrosion- and heat-resistant castings. As to its influence on graphitization, one per cent copper is equivalent to 0.1 to

0.2 per cent silicon. In malleabilizing, it may be, therefore, both a hindrance and a help, tending to make the iron mottled in casting but shortening the annealing time. The strength of malleable iron containing about one per cent copper can be increased 2000 to 8000 lbs. per sq. in. by precipitation hardening, a treatment usually carried out by heating for one hour at 1380° F and reheating for 3 hours at 930° F.

Effects of Molybdenum—Molybdenum is rarely found in pig iron, but is added in the ladle as ferromolybdenum in cupola practice, or in the furnace as ferromolybdenum or calcium molybdate in air- and electric-furnace practice. It strengthens and toughens the metal, and is added in amounts of 0.30 to 1.25 per cent to increase strength, hardness, and resistance to shock. It is credited also with preventing cracking. It does not decrease the shrinkage on solidification, but does decrease slightly the contraction following solidification. Its effect upon graphitization is slight, and it appears not to affect the amount of combined carbon, but does increase the depth of chill when added in amounts of 0.25 to 0.60 per cent. It increases resistance to wear, hinders graphitization somewhat, has little effect on growth, improves the properties at high service temperatures, and promotes uniformity in mechanical properties as between large and small sections.

Effects of Titanium and Aluminum—Both of these elements have been added to cast iron, but only titanium is used regularly. Both are reported to promote graphitization, titanium decreasing the size of the graphite flakes. A little titanium, 0.05 to 0.10 per cent, is common in pig iron, and its effect appears to be generally beneficial. The addition of titanium to cast iron is reported to impart greater tenacity and resistance to wear.

Influence of Vanadium—Vanadium has been added to cast iron in amounts of 0.10 to 0.15 per cent. It is an expensive addition, and its chief effect seems to be that of opposing graphitization.

Effects of Special Additives—Various chemical elements other than those discussed above are added to iron for casting to effect changes in microstructure, improve mechanical properties, and so on. Such elements may be added singly or in various combinations. A notable instance is that of adding magnesium or cerium alloys to iron to produce what is designated as "nodular iron;" this practice will be described later in this chapter under the heading of "Kinds and Uses of Iron Castings."

IRON-FOUNDRY MELTING METHODS

The chapter on pig iron describes the manufacture of iron used in the production of iron castings. The pig iron for castings may be melted in one of several types of furnaces, the cupola, the air furnace or the electric furnace, though the cupola is the principal source of molten metal for iron castings. In the case of certain alloy and high-test iron castings, the metal is frequently duplexed; i.e., melted in a cupola and further processed in an electric furnace. The open-hearth furnace also has been used for melting iron for castings, but its use for this purpose is limited.

The Cupola—The cupola resembles a miniature blast furnace. It differs primarily in that pig iron and steel scrap replace iron ore in the charge. The cupola is lined with fireclay or firestone refractories. Since, in most installations, no water cooling is utilized in the melting zone, the lining has to be repaired with plastic-fireclay patching between periods of operations. In the few installations where water-cooling of the melting zone is employed, such frequent repair of the lining is not re-

quired. The charging door is located on the side of the cupola near the top. The cupola is supported by legs, permitting the use of a drop bottom which facilitates the removal of the remaining burden after the last charge has been tapped. Intermittent operation is the general rule, but continuous operation is possible.

The charge is composed of coke, steel scrap, iron scrap and pig iron in alternate layers of metal and coke. Sufficient limestone is added to flux the ash from the coke and form the slag. The ratio of coke to metallics varies, depending on the melting point of the metallic charge. Ordinarily, the coke will be about 8 to 10 per cent of the weight of the metallic charge. It is kept as low as possible for the sake of economy and to exclude sulphur and some phosphorus absorption by the metal.

During melting, the coke burns as air is introduced at a 10 to 20 ounce pressure through the tuyeres. This melts the metallic charge and some of the manganese combines with the sulphur, forming manganese sulphide which goes into the slag. Some manganese and silicon are oxidized by the blast and the loss is proportional to the amount initially present. Carbon may be increased or reduced, depending on the initial amount present in the metallic charge. It may be increased by absorption from the coke or oxidized by the blast. Phosphorus is little affected, but sulphur is absorbed from the coke. Prior to casting, the slag is removed from the slag-off hole which is located just below the tuyeres. The molten metal is then tapped through a hole located at the bottom level of the furnace. The depth between these two tapping holes and the inside diameter of the furnace governs the capacity of the cupola.

The Air Furnace is a type of reverberatory furnace somewhat similar to the puddling furnace described in Chapter 11. It has a fireplace at one end, the stack at the other end, and between them a hearth covered by a roof sloping toward the stack. A cross, or "bridge," wall near the stack (the flue bridge) and another next to the fireplace (the fire bridge), together with the lining (usually of silica sand) form a rectangular basin which holds the charge. A removable-bung type of roof is used to permit charging large pieces through the top with a crane. Coal, fuel oil or gas are used as fuel, the liquid or gaseous fuels being preferred. When coal is used, the fireplace is constructed and manipulated to serve as a crude producer. About 15 per cent of the carbon, 30 per cent of the silicon, 45 per cent of the manganese, and 1 to 2 per cent of the iron of a pig-iron charge are oxidized in the air furnace, the exact amounts varying with the composition of the charge and the oxidizing conditions of the flame.

The Electric Furnace—A description of the arc-type electric furnace, which is used to a limited extent for melting iron for iron castings, is given in Chapter 16.

KINDS AND USES OF IRON CASTINGS

One of the principal reasons for using iron instead of steel castings is the fact that cast iron is more resistant than cast steel to warping and cracking in the presence of heat. There are other reasons for the use of iron castings, such as hardness and wear resistance, damping effect, corrosion resistance, intricacy of shape and massiveness of the casting. The various kinds of iron castings are: chilled-iron castings, malleable castings, alloyed-iron castings, gray-iron castings, and nodular-iron castings. Among the innumerable uses may be mentioned pipe, rolls, permanent molds, ingot molds and stools, sanitary ware, engine blocks and all kinds of machinery parts. A few of the various kinds of iron castings, with their compositions, properties and uses, are

*T.C. = Total carbon content; G.C. = Graphitic carbon content; C.C. = Combined carbon content

given in Table 18—III. Further details may be found in "Cast Metals Handbook" published by the American Foundrymen's Association.

Chilled-Iron Castings are extremely hard on the surface. They are made by melting iron of certain compositions, and casting the molten metal in such a way that the parts to be hardened will be solidified on contact with a metal or graphite block capable of abstracting heat rapidly and thus causing quick cooling. Chilled-iron castings are made of ordinary low-silicon iron and of irons alloyed, usually, with nickel and chromium. The chilled surface is very hard, and when fractured, shows white for a distance beneath the chilled surface varying with the rate of cooling and the composition of the iron; hence, such irons are commonly spoken of as chilled iron. The hardness and the white fracture are due to the fact that all the carbon, in the clear chill at least, is in combined form, the rapid cooling preventing the separation of graphite. In heavy sections, the clear chill will extend only a short distance, $\frac{1}{8}$ inch to 2 inches from the surface, where it merges into mottled, then into a gray appearance, all these structures being the result of varying the rate of cooling. Such castings are used for rolls and various other articles which require a hard, wear-resisting surface. All three types of furnaces are used for melting, depending upon the kind of iron and other factors.

Malleable Castings, while not strictly malleable, are soft and can be bent without breaking. They are of two kinds, known as **white heart**, or **European**, and **black heart**, or **American**, these terms indicating differences in the process and the products and countries of origin. As an initial step in making malleable castings, a charge consisting of malleable grades of pig iron (10 to 15 per cent), steel scrap (35 to 40 per cent), and cast-iron scrap, (45 to 55 per cent), consisting of feeders, runners, sprues, and defective castings, may be melted to give metal containing 2.25 to 3.00 per cent carbon, 0.3 to 0.50 per cent manganese, 0.05 to 0.08 per cent phosphorus, 0.06 to 0.11 per cent sulphur, and 0.60 to 1.15 per cent silicon, the exact composition, particularly in regard to silicon, being varied according to the thickness of the section being made. If the carbon is under 2 per cent, graphitization in annealing is slow and if the carbon is near 4 per cent, graphite may be formed in casting. To prevent the latter occurrence, the silicon is lowered as the carbon is increased in a given casting, if the iron must be white all the way through after casting, with all the carbon in the combined form. When the iron has melted, it is tapped and cast in well-prepared green-sand molds, made about $\frac{1}{4}$ inch per foot oversize to allow for total shrinkage, or liquid-to-solid contraction. When cool, the castings are removed from the molds and, unless finish is of no consideration, cleaned by tumbling, sand blasting, pickling, or hand scouring. The castings next are packed carefully in annealing boxes or pots with an oxidizing agent, such as roll scale or crushed furnace slag for white-heart castings, or with nonoxidizing materials such as blast-furnace slag, fine sand, etc., for black-heart castings. The packed castings then are placed in an annealing furnace and heated gradually to about 900° C (1650° F) for white-heart castings or to near 871° C (1600° F) for black-heart castings. The former are held at this temperature 3 to 5 days, during which time the iron carbide is eliminated almost completely by a process of migration and surface oxidation of the carbon to CO or CO₂, leaving a metal similar to soft steel but of much coarser grain and less ductile. Since the migration of the carbon is very slow, only thin castings can be decarburized successfully or "malleableized" by this process. Black-heart castings

are treated by an "annealing cycle," requiring about 30 hours for heating to temperature, about 45 hours holding at temperature, 30 to 35 hours for cooling to and holding at 650° C (1205° F) and 5 hours for cooling to handling temperature. In this cycle, the combined carbon is completely graphitized, causing the casting to grow slightly and leaving the iron as ferrite. But instead of forming plates, the graphite is dispersed in a very finely divided form known as temper carbon, which, under the microscope, is seen as black spots distributed in haphazard fashion throughout the metal except near the surface of the casting where the metal may be partly or wholly decarburized. Thoroughly malleableized castings have a yield point of about 27,000 lbs. per square inch, and a tensile strength of about 45,000 lbs. per square inch. Some standard specifications require a yield point of more than 32,000 lbs. per square inch (32,500 and 35,000 minimum for two grades), and a tensile strength of more than 50,000 lbs. per square inch (50,000 to 53,000 minimum for two grades). The modulus of elasticity is about 25,000,000 lbs. As to ductility, standard specifications require a minimum elongation of 10 to 18 per cent in 2 inches. Castings that have been malleableized are immune to growth.

Alloyed Castings—Alloyed irons are used most extensively for applications where resistance to wear, to heat (including growth), and to corrosion, along with the high strength of the alloyed iron, rigidity, "damping" of vibrations and amenability to heat treatment are of prime importance. They are produced and used extensively by the steel industry but are used most widely by the automotive industry for purposes where the above properties are a requirement. The alloying elements used are silicon, nickel, chromium, molybdenum, copper and titanium, in amounts varying from a few tenths to 20 per cent or more. They may be classed as: (1) low-alloyed gray-iron castings, (2) high-alloyed gray-iron castings, and (3) austenitic alloy castings, the latter containing sufficient alloying elements to hold the iron in the austenitic condition. These are used for resistance to corrosion, both atmospheric and chemical; for resistance to heat, including oxidation and growth; and for their high thermal coefficient of expansion. Many of these irons are patented compositions and are sold under various trade names, such as Ni-resist, Causal metal, Silal, Ni-crosilal, etc.

Gray-Iron Castings—Gray-iron castings are made of pig iron, of mixtures of pig iron and steel, or of mixtures of pig iron, steel and other metals in smaller amounts, and have been referred to as semi-steel, high-test iron, and alloy iron. They are frequently sold under trade names, such as Meehanite, Gunite, Ermalite, Ferrosteel, Gun-iron, etc. Chemically, gray-iron castings include a large number of metals covering a wide range in composition, with carbon varying from 2 to 4 per cent, and silicon from 0.5 to 3 per cent, with small amounts of Ni, Cr, Mo, and Cu frequently added. Grouped according to uses, they include (1) pipe-foundry castings, (2) sanitary ware, (3) automotive castings, (4) locomotive castings, (5) light machinery, (6) heavy machinery, (7) miscellaneous shapes.

Mention has been made of the use of cast iron for ingot molds and stools. If available, molten iron direct from the blast furnace may be used instead of cupola iron because of its lower cost and high percentage of graphitic carbon. In some cases where iron direct from the blast furnace is not available, cupola iron is used for this purpose; however, studies invariably indicate that blast-furnace iron produces a mold with longer life than those produced with more refined cupola iron. The composition of the iron, pouring temperature and their

relation to ingot-mold and stool life require considerable study; however, the consensus of opinion of mold makers in this country indicates that the composition should be about as follows:

Silicon	1.25 to 1.75%
Phosphorus	0.120 to 0.140%
Sulphur	0.035 to 0.050%
Manganese	1.00 to 1.40%

A casting temperature of 2300° F to 2350° F is desirable.

Pipe-foundry castings include cast-iron pipe and fittings. A great part of cast-iron pipe now is cast centrifugally from ordinary iron containing less than 0.1 per cent sulphur, under 0.9 per cent phosphorus, with carbon and silicon controlled to give the required mechanical properties. When not centrifugally cast, the molten metal is poured into cored dry-sand molds supported in a vertical position, those 18 inches or more in diameter being cast with the hub end down.

Nodular-Iron Castings—Nodular iron, also called ductile iron and spheroidal graphite iron, is a relatively new grade introduced around 1948; it has been used for castings having sections from ¼ inch up to 40 inches thick. It is produced by treating molten iron that normally would produce a soft, weak, gray iron casting with cerium or magnesium alloys. The addition of these special alloys results in castings which have the carbon present in spheroidal form. Castings so made have relatively high strength and better ductility than ordinary gray iron. Pearlitic nodular irons have a tensile strength in excess of 80,000 lb. per sq. in., with an elongation of at least 3 per cent, while ferritic grades, having tensile strengths of over 60,000 lb. per sq. in., will show an elongation of from 10 per cent to 25 per cent. For economy, iron having a sulphur content below about 0.15 per cent is required for the process. Several types of matrix structures can be developed by alloying or heat treatment; the pearlitic and ferritic matrices were mentioned above. As this type of iron has been discussed extensively in recent literature, no further details will be given here.

IRON-FOUNDRY MOLDING AND CASTING PRACTICE

Molding practice for iron castings is somewhat similar to that already described for steel castings in Section 1 of this chapter, the chief differences being in the preparation and types of sand and the placement and size of gates and risers, the latter being modified by reason of the lower shrinkage in cast iron.

The scope of this book does not permit more than a brief description of the casting of iron castings. The metal is cast in one of five types of molds: namely, (1) **green-sand molds**, made of moist sand which is rammed about a pattern (usually of wood) in a "flask" of wood or iron, and the metal is poured with the mold in the condition as rammed; (2) **dry-sand molds**, made up like green-sand molds, but dried before they receive the metal; (3) **loam molds**, made up of loam (a kind of low-grade sand) which, for heavy castings, is backed with brick and faced with other more refractory material; (4) **permanent molds** or **semi-permanent molds**, which have become more and more popular for certain applications; and (5) **shell molds** which are a recent development.

The permanent mold is a cast-iron or graphite mold into which the molten iron is poured. The semi-permanent mold is built up of cast iron and sand, the latter having to be replaced after use. In both the latter cases, the molds are prepared with a graphite coating and warmed to 150 to 200° F before the hot metal is

poured into the mold. Shell-molding techniques are described in numerous recently published articles and papers and will not be discussed in detail here; briefly, shell molds are made by applying a coating of sand mixed with a synthetic resin or other suitable binder to a prepared pattern and then "curing" the coating by heating to form a solid shell that can then be stripped from the pattern. Shell molds are used in the production of steel and nonferrous castings, as well as iron castings.

TESTING OF CAST IRON

The tests most commonly employed for gray cast iron are the tension test, transverse load and deflection (measured bend) test, and hardness (Brinell and file) tests. In making tension tests, standard test specimens are machined from a standard cast test bar, and "pulled" in a tensile-testing machine until the piece breaks, the load calculated to pounds per square inch being taken as the tensile strength. In short-time tension tests, most grades of cast iron show no point corresponding to the yield point of steel and very little, if any, elongation or reduction of area. The form of specimen used for making tensile tests is somewhat different from that used for testing steel. There are three standard sizes; viz., 0.505 inch, 0.750 inch, and 1.25 inches in diameter (at the center), the diameter being varied with the thickness (and design) of the castings they represent. As standard specifications do not require the measurement of elongation but only the tensile strength, specifications covering the lengths of specimens merely state that the affected test length shall not be less than the diameter. The tensile strength varies: (a) with the diameter of the test bar, being higher for bars of smaller diameter and lower for bars of greater diameter; (b) with the temperature above 250° F, being almost constant up to 600° F and decreasing rapidly above 800° F; and (c) with the time after casting, most castings increasing in strength with age. This change is attributed to relief of casting strains, which may be relieved also by tumbling and by heat treatment. The relief of strain by aging is called **seasoning**.

Transverse testing consists of placing a standard bar upon supports 12, 18, or 24 inches apart, then either applying a specified load and noting the deflection, which is measured in inches, or of loading until deflection occurs and then gradually increasing the load till the specimen breaks. With the latter procedure, the **modulus of rupture** is found from the equation
$$M R = \frac{2.546 L S}{D^3}$$

where $M R$ = modulus of rupture, L = distance between supports in inches, S = the breaking load, and D = the diameter of the test bar.

In the Brinell hardness test, a special machine is used to apply a load of 3,000 kg. to a steel ball 10 mm. in diameter, resting on a filed-smooth surface of the iron to be tested. The Brinell number is taken as the quotient of the load divided by the area of the impression made by the ball. Thus, small numbers up to 100 indicate softness, while high numbers (400 to 600) indicate great hardness.

Chapter 19

PLASTIC DEFORMATION OF STEEL

SECTION 1

INTRODUCTORY

In discussing the subject of plastic deformation in a book of this nature, it is necessary to point out that it is possible to consider only the major aspects of this very complex and very important behavior of metals. There is a voluminous literature on the subject to which recourse should be had if any extensive study of the subject is contemplated. The contents of this chapter are intended to serve as an elementary introduction to some of the concepts that are useful in understanding how solid metals can be worked to change their shape into useful articles.

The process of shaping steel by casting (pouring the molten metal into suitable molds where it is allowed to solidify in the desired form) was described in previous Chapter 18. The very large majority of the steel produced, however, is processed by forging, rolling, or other forms of mechanical working, to give it the desired shape. Steel so worked is called **wrought steel**. The numerous means of working involved in shaping steel are categorized as **mechanical treatment**. The present chapter will briefly discuss some of the properties and characteristics of steel that enable it to undergo a change of shape without rupturing, and will summarize the principles of the more important methods used to shape steel. More detailed discussions of most of the methods will appear in subsequent chapters.

Objectives of Mechanical Treatment—The primary objective of mechanical treatment, then, is the production of wrought steel in shapes and sizes that adapt it to specific end uses. It is a fortunate circumstance that the operations involved in the mechanical shaping of steel, if properly performed, result in the attainment of a second objective—that of improving the quality of the steel by altering its mechanical and physical properties.

All wrought steel originates in the form of ingots. Ingots, as described in the next chapter, are large castings of relatively simple shape which possess certain inherent weaknesses and defects. These shortcomings can be eliminated, to a great extent, through proper mechanical treatment as the metal is reduced, through successive stages of working, into finished products. The amount of work performed, the rate at which it is carried out, the temperature of the steel while being worked, and the rate at which it cools to ordinary temperature after working, all affect the ultimate properties of the finished wrought-steel products.

Crystalline Nature of Steel—Solid steel is crystalline in nature; that is, it is made up of innumerable allotriomorphic crystals called grains. The grains possess all of the characteristics of true crystals except the regularity of external shape associated with perfect (idiomorphic) crystals. Some of the properties and the structure of crystals were discussed in Chapter 2 under "Crystallography."

Elasticity and Plasticity—It was stated in Chapter 2, and is elaborated in Chapter 49, that steel, when subjected to loads under the elastic limit, will be deformed by an amount proportional to the load. However, when the load is removed, the steel will resume its original shape and dimensions, and no permanent distortion occurs. This restorative ability is called **elasticity**.

If, however, the metal is subjected to loads or forces exceeding the elastic limit, permanent distortion will take place. Between the elastic limit and the load that causes actual rupturing of the steel, the metal "flows" under load in an attempt to adjust itself to the imposed forces. This ability to react to imposed loads above the elastic limit by changing shape permanently without rupturing is referred to as the **plasticity** of steel, and the mechanism by which shape is altered without rupture is called **plastic deformation**.

Mechanism of Plastic Deformation—The ability of solid metals to behave in a plastic manner is related to their crystal structure. *Elastic* behavior may be conceived as representing simple distortion of the crystal lattice under load; when the load is removed, the lattice is restored to its original dimensions. However, when plastic deformation occurs, the crystals themselves are distorted. A simplified explanation of how such permanent distortion can occur without actually rupturing the crystals is as follows:

The locations of atoms in the crystal lattice define certain planes along which parts of each crystal can be displaced in relation to adjacent parts without rupturing the crystals. These displacements result in permanent deformation of the crystals. The planes along which displacements (called "slip") can occur lie in definite directions related to the crystallographic axes of each crystal, and are limited in number. The effect of plastic deformation on metals at ordinary temperatures will be considered first.

Strain Hardening—It is an interesting fact that slip can occur only to a definite extent along any one plane. Any further deformation of a crystal must take place through slip on other planes within that crystal. Eventually, if stress above the elastic limit is applied, either continuously or in a succession of applications, all possible slip will have occurred on the available planes, and any additional application of sufficient stress will rupture the crystal instead of deforming it further. Each increment of slip in its crystal system reduces the ability of a metal to deform further plastically, and is reflected in a change in the properties of the metal. In general, the yield strength, tensile strength and hardness of the metal are increased, while the ductility is decreased—all to a degree proportional to the amount of plastic deformation that has occurred. This phenomenon is called **strain hardening**, and metals which have been

strain hardened contain internal stresses resulting from deformation.

Recovery—In some metals which have been strain-hardened, the metal atoms possess sufficient mobility at ordinary temperatures to move about (through a mechanism called **diffusion**) and assume positions that eventually tend to relieve the internal residual stresses. This phenomenon is called by the scientific name of **recovery**. Among the more common metals at ordinary temperatures the rate of recovery is so slow that it has little practical significance. By heating mechanically-worked metal, the rate of recovery can be increased many-fold, and most of the residual internal stresses are eliminated in a comparatively short time.

Recrystallization—If mechanically worked strain-hardened metal is heated to higher and higher temperatures, a temperature level is reached where a second process—quite different from recovery—occurs. This is called **recrystallization**, and results in the complete rearrangement of metal atoms to form an entirely new set of crystals, and elimination of the strain-hardened condition.

The greater the degree of prior plastic deformation, the larger will be the amount of stored energy of distortion in the metal, and the lower will be the temperatures at which recrystallization begins.

Hot Working and Cold Working Defined—From the foregoing, it is evident that if a metal was worked me-

chanically at a high enough temperature, any strain hardening that occurred during working would be eliminated almost instantly before the metal cooled to ordinary temperatures. On this basis, **hot working** is defined as permanent deformation of a metal at temperatures such that no strain hardening is evident in the wrought metal after it cools to room temperature. **Cold working**, conversely, leaves the metal in the strain-hardened condition. In the case of steels, the effects of cold working can be removed entirely by heat treatment (see Chapters 34, 40 and 42).

In either hot working or cold working, if stresses of a sufficient magnitude to change its shape are applied to a piece of steel, its over-all change in dimensions represents the aggregate of the tiny displacements which occurred in individual crystals making up the piece.

Actually, as stated in the section on "Crystallography" in Chapter 2, the simplified mechanisms described above are complicated by many factors which cannot be discussed in detail here.

Many theories have been advanced for estimating the strength of the facilities and the power required for the plastic forming of steel, but no one of them has as yet been demonstrated to be completely valid. The chief reasons for this situation seem to be the lack of physical data for evaluating the deformation resistance of steel and the friction coefficients which obtain under the conditions of actual operations.

SECTION 2

HOT WORKING AND ITS EFFECTS

The upper temperature limit for the hot working of steel depends upon the carbon content (for plain carbon steels) because hot working must be carried out at a safe temperature below the melting point of a given steel. The upper limit for starting hot work may be considered to be between 2300° and 1950°F, the higher temperatures being used for steels of the lower carbon contents. At such temperatures, the steel is composed entirely of austenite (see Chapter 42).

The chief benefit derived from proper hot working of steel is the refinement of its grain structure. In the case of ingots, hot working also welds unoxidized cavities shut, tends to eliminate porosity if it exists in the center of an ingot, and tends to lessen segregation.

During hot working, the metal crystals (grains) are

deformed or fragmented, and a strained condition is set up in the steel. The relatively great mobility of atoms at hot-working temperatures permits the strained condition to be relieved by the formation of new small grains of austenite from the deformed, fragmented crystals either during or immediately after hot working (Figure 19-1). The new grains grow in size at a rate which is greater the higher their temperature and the longer the time they have to grow at that temperature. The new small grains are equi-axed and are randomly oriented. As the hot-worked steel cools to room temperature, it passes through the critical temperature range (Chapter 42) and a new crystal structure is produced through allotropic transformation.

Without discussing the somewhat complex effects of

Fig. 19-1. Diagrammatic representation of the combined effects of the mechanisms of hot rolling and recrystallization on the grain structure of steel. (Grain size is shown much exaggerated for clarity.)

working steel in the critical temperature range, and the resulting microstructures, the lower critical temperature may be stated to be the practical lower limit for hot working plain carbon steel, regardless of its carbon content. In the case of alloy steels, the alloying elements affect the transformation temperatures, and their effects, along with other factors, will establish the proper minimum finishing temperature.

Finishing Temperature—Hot work is usually performed in a succession of steps, such as a series of passes in rolling or a series of blows or squeezes by a hammer or press. The more frequent the applications of pressure and the lower the temperature at which they occur (but still above the lower critical temperature), the smaller the grain size will be at the completion of hot working. The more frequent the pressure applications, the less time the new grains have to grow between successive workings. The lower the finishing temperature at which the working is completed, the slower the new grains will grow. Also, the greater the amount of hot work, the finer will be the ultimate grain size. The best mechanical properties can be expected from steel having a fine (small) grain size.

If the temperature at which hot working is begun could always be selected so that the piece would be finally shaped when it reached the lower critical temperature, the steel would have the minimum grain size and the best possible mechanical properties obtainable by hot working and still be in an unstrained condition. In actual practice, shapes of large size or great intricacy require a high degree of plasticity obtainable only by starting hot working at a high temperature in order that the metal will flow or work with relative ease without requiring excessive amounts of power for working or too long a time for effecting the desired shaping. Under such conditions, working is usually completed at temperatures well above the lower critical temperature. Discrimination is required to establish heating and working schedules for hot working that will give the steel its best properties within practical economical and metallurgical limits.

Fiber and Banding—Even after hot working, when the microscopic grains have become entirely recrystallized, there still persists in the hot-worked piece a certain elongated structure, which affects the mechanical properties in some degree. This elongated structure has its origin in two features of the ingot structure. One feature is the presence of microscopic foreign matter or particles, called non-metallic inclusions; it is impossible to produce steel absolutely free from these inclusions. Such inclusions (or regions of inclusions) are elongated as the steel is worked, and result in a condition sometimes called **fiber**. In practically all rolled steel, or any steel hot-worked principally in one direction, the mechanical properties (especially the ductility) in the direction of working are different from those in a perpendicular direction. Thus, if a tension test is made in the longitudinal direction (that is, parallel to the direction of rolling or working) the elongation of the test piece (before rupture) will be greater than when the test is made transversely (perpendicular to the direction of rolling or working). This "directional" phenomenon is thought to be associated with fiber. Another appearance thought to influence the directional behavior is **banding**. This is the second phenomenon inherited from the ingot. If a rolled product (e.g., a bar or a plate) is cut longitudinally, and this section is examined with a microscope, the banded structure, if present, will be seen to consist of a myriad of bands parallel to one another and parallel to the direction of rolling. They are due to slight differences in chemical composition from edge to center of each band.

These slight differences in composition had their origin in the solidification process in the ingot, inasmuch as each grain in the ingot shows such differences. The grains in the original ingot were by no means elongated and parallel, but became so because of the rolling. The spontaneous recrystallization which occurs in hot rolling is unable to affect these minute chemical segregations, which therefore remain in the banded condition. The banded condition is believed to contribute to the directional phenomenon in mechanical properties, described above. The directional differences are found not only in the tension test, but also commonly in the notch-impact test.

PRINCIPAL METHODS FOR HOT WORKING

The principal methods of forming steel by hot working are hammering, pressing, rolling and extrusion. Hot working by the first two methods is called forging.

Forging may be performed under hammers, in mechanical presses and upsetters or by a method known as roll forging. Pressing generally includes the manufacture of forged articles in hydraulic presses. Extrusion usually is performed in hydraulic presses which force the hot plastic steel through a die. Rolling is performed in rolling mills of a variety of types described in detail in various other chapters. The present discussion will be limited to general descriptions of the various types of hot-working equipment and some of the principles of their operation.

Hammering—Hammering was the first method employed by man in shaping metals. The first forging was done by hand hammers wielded by workmen.

The first known power hammer, called a **tilt hammer**, was built in England. It was driven by water power and consisted of a beam of wood, hinged at one end and provided with an iron hammer head or die at the opposite end. At an intermediate point between the hinged end and the free end carrying the hammer head, cams on the revolving shaft driven by the water wheel alternately raised the free end and allowed it to fall upon an anvil or die fixed upon a suitable foundation. This was a crude tool compared to the steam hammers now used.

The first steam hammer was built in France during 1842. It consisted of a two-piece frame, constructed so as to support a vertical steam cylinder, fitted with a piston and piston rod, directly over a die or anvil. To the piston rod of the steam cylinder was attached a tup or hammer head. By admitting steam to the cylinder below the piston, the hammer was raised for any desirable length of stroke and then allowed to drop upon the work piece supported on the anvil or bottom die.

In order to increase the striking force of the steam hammer above that derived from gravity alone, there was developed the **double-acting steam hammer**, in which steam can be admitted above the piston also and employed both on the downward stroke as well as for lifting the tup. This type of hammer is illustrated in Chapter 32, relating to the forging of axles. The first double-acting steam hammer was built at Midvale, Pennsylvania, in 1888.

A variety of other types of forging equipment employing the impact principle for forming hot steel have been developed but cannot be described here. Descriptions are available in reference works listed at the end of this chapter.

Pressing—The hydraulic forging press is an English invention dating from the year 1861. It was introduced into the United States about 1887. It consists (see Figure 19-2) essentially of a hydraulic cylinder supported by

FIG. 19-2. Hydraulic press in operation, forging a massive ingot supported on a porter bar which, in conjunction with the link-chain support, permits manipulation of the ingot as desired.

two pairs of steel columns which are anchored to a single base casting of great weight and strength. The piston or ram of the cylinder points vertically downward and carries the upper forging die, which is directly above a stationary die resting on the base casting to which the columns are attached. By admitting water under high pressure to the cylinder at its top, the ram carrying the upper die is forced down upon the material to be forged, which rests upon the lower forging die. Small auxiliary cylinders lift the ram after each application of pressure.

The pressure, which must be very high if the forging press is to do effective work, is increased gradually and maintained until the metal yields. In practice, it has been found that the lowest pressure that can be effective in shaping steel at a full forging heat is about 1.2 tons per square inch, but the pressures employed in actual work often will exceed 13 tons per square inch.

Extrusion—The hot-extrusion process consists of enclosing a piece of metal, heated to forging temperature, in a chamber called a "container" having a die at one end with an opening of the shape of the desired finished section, and applying pressure to the plastic metal through the opposite end of the container. The metal is forced through the opening, the shape of which it assumes in cross-section, as the metal flows plastically under the great pressures used.

The equipment and methods for carrying out one type of hot extrusion are described in detail in Chapter 41.

Mechanical Forging—Many hot forgings are produced on mechanical presses. In machines of this type, pressure is applied to a vertical ram (carrying the upper forging die) through a connecting rod from a crankshaft. The heated work piece rests on the bottom die. The stroke of such a press is limited to the "throw" of the crankshaft.

Upsetting—A special type of mechanical press is the upsetting machine, in which the piece to be shaped is clamped between two dies with vertical faces and

shaped by the action of a tool on a ram operated by a crankshaft. The ram of the upsetting machine operates with a horizontal, instead of vertical, stroke.

Hot Rolling—Of all the known methods of shaping steel, that of rolling, as introduced by Henry Cort in 1783, has come to be employed the most extensively. Though Cort is credited rightly with being the "father of modern rolling", because of his successful development of mills employing grooved rolls, the use of this principle in shaping metal antedates his mill by many years. There are records, for example, to show that in the year 1553, rolls were employed in France to produce sheets of uniform thickness for the stamping of gold and silver coin. In Sweden, rolls were employed to produce certain sections prior to the year 1751, and even at that time the assertion was made that as many as twenty times more bars could be reduced in a given time than could be shaped under the tilt hammer of those days. From the days of Cort to the present time, the rolling mill has passed through a rapid process of development, not only in the size, power and productive capacity of mills, but also in their design and in the increasing variety of shapes of sections that can be produced.

Mechanical Principle and Effects of Rolling—The process of shaping steel by rolling consists essentially of passing the material between two rolls revolving at the same peripheral speed and in opposite directions, i.e., clockwise and counterclockwise, and spaced so that the distance between them is somewhat less than the height of the section entering them (Figure 19-3). Under these conditions, the rolls grip the piece of metal and deliver it, reduced in cross-sectional area and increased in length. The extent of sideways or lateral spreading (called spread) is found to depend mainly upon the amount of reduction and the shape of the cross section entering the rolls; thus, in rolling plates of considerable width, the actual total spread is independent of the width, and actually may be less than that resulting from the first pass in the reduction of small, square

FIG. 19—3. Diagram illustrating the action of plain rolls upon a piece of hot, plastic steel of originally square cross-section.

billets, especially if the percentage reduction in cross-sectional area of the latter is great.

The turning of the rolls in contact with the work introduces a frictional force which acts along the arcs AB and A'B' of Figure 19—3, and is proportional to the pressure between the rolls and the piece. This pulls the work into the opening between the rolls, against the wedging action of the tapered section entering the rolls. The piece is delivered at a higher speed than the roll-surface speed; it enters at a velocity lower than the roll-surface speed. The ratio of the speed with which the work leaves the rolls to the surface speed of the rolls themselves is called the **forward slip**. Evidently, there must be some point between A and B and A' and B' where the speed of the bar is equal to the roll-surface speed. This point, indicated on the drawing by N and N', is called the **neutral point**, which coincides with the point of maximum pressure. The arc AB is called the **contact arc**, and its including angle OAB the **contact angle** or **rolling angle**. When this angle is the maximum at which the piece will enter (without pushing), it is called the **angle of bite**. The area of steel under the contact arc is called the **contact area**, which is projected to show the spreading that may occur.

Effects of Work Temperature—The effects of rolling with respect to changes in physical dimensions of the piece are influenced very markedly by the temperature of the piece being rolled with respect to both degree and uniformity of heating. Additional plasticity imparted to steel by relatively slight increases in temperature lessens the power required for rolling and increases the ease with which it can be made to flow plastically in the desired directions. Chemical composition of a particular steel and the nature of the rolling operation to be performed may limit, respectively, the maximum and minimum rolling temperatures that are applicable.

Effects of Roll Diameter—Small diameter rolls require less force than rolls of larger diameter to effect a given reduction. Advantage is taken of this fact in four-high

and other mills employing small-diameter work rolls backed up by heavier rolls that prevent the smaller rolls from bending. Small rolls lessen the separating force for two reasons: first, the area of contact is less so that, with a given pressure, the total force required is less; and second, the required average pressure is less because the smaller area of contact reduces the total frictional forces.

Miscellaneous Hot-Working Methods—**Rotary swaging** is performed to taper the end of bars, wires and tubes. The machine in which the work is done has two or four shaped dies, in opposing pairs, suitably mounted in a rotating ring. As the ring rotates, alternate pairs of dies are forced against the metal being swaged, the resultant pressure shaping the piece. Such a machine is illustrated in Chapter 41 (Figure 41—40).

In **hot spinning**, which is limited to shapes symmetrical about the spinning axis, the heated piece to be shaped is mounted in a lathe or similar machine that can rotate it rapidly. A tool is then brought to bear against the spinning piece and, by manipulating the position and pressure of the tool, the work piece can be shaped. For example, bowl-shaped sections, such as flanged and dished heads, can be formed from flat, circular plates by spinning.

Many steel parts are formed hot from plates and sheets by **hot deep-drawing** operations that would be impracticable if the material were at room temperature. Roof ribs for railroad box cars, one-piece gates for hopper cars, deep bowls, etc., are typical. The heated steel is formed in hydraulic or mechanical presses equipped with forming dies that produce the desired shapes. Another example is the manufacture of closed-end cylinders by a combination of hot cupping and drawing operations, described in Chapter 41.

Roll forging, **die rolling**, and other hot-forming processes of limited use have not been included in the foregoing descriptions. Reference to these processes can be found in various handbooks.

COMPARISON OF METHODS FOR HOT WORKING

It is a very difficult matter to make a fair comparison between rolling and forging, or even between hammer and press forging. Each method has a field of its own with rather well-defined boundaries. Many irregular shapes are so intricate in design that rolling or extruding them is out of the question, and such shapes must be formed under the hammer or in the press. Certain crankshafts or a claw-hammer head serve as examples of these classes of shapes, which can be produced by no other form of mechanical working than by the forging method.

Tonnagewise, the hammer and the press are both slower and more expensive to operate than rolls. Special care must be given to all phases of the forging operation, including heating for forging. It is, perhaps, this meticulous care required to produce high-quality forgings that has given rise in some quarters to the belief

that forged articles always are superior to rolled articles. Assuming that a given section can be produced by either rolling or forging, and that an equivalent amount of attention is given to all details of both processes with regard to heating, proper speed and amount of reduction, etc., the quality of rolled material can be equal to that of forged product.

With the complex stress-strain relationships involved in plastic deformation in hot working, and the basic differences in the nature of the major hot-working processes, direct comparison is difficult. However, studies have shown that the effects of rolling and pressing are comparable, provided equipment for carrying out both processes is of comparable capacity and the same sized pieces are being worked.

Rolls have the distinct advantage of speed of production where the shapes involved are of a nature suited to rolling. There is one field of operation in which rolling, hammering and pressing all can be applied; this is the shaping of blooms and billets from ingots.

SECTION 3

COLD WORKING AND ITS EFFECTS

In contrast to hot working, the effect of the cold working of steel by rolling, drawing or other means, is evidenced by changes in the physical structure of the material by grain distortion and is accompanied by changes in the mechanical properties due to strain hardening. Cold working, generally applied to bars, wire, tubes, sheet and strip, is a process of reducing the cross-sectional area by cold rolling, cold drawing, or cold extrusion. Cold working is employed to obtain the following effects: improved mechanical properties, better machinability, special size accuracy, bright surface, and the production of thinner gages than hot work can accomplish economically. The present brief discussion will be supplemented in later chapters by discussion of methods and effects of cold working various steel-mill products.

Steel cold worked in the temperature range between about 400° and 750°F may become brittle and difficult to work. This temperature range is called the "blue-brittle range," a name given it by early metalworkers because steel with a clean surface heated in that range assumes a blue color due to oxidation.

A special technique called "warm working" is described in Chapter 41.

While steel can be cold worked at temperatures just below the lower critical temperature, better control of grain size, surface condition and dimensions can be effected by working at atmospheric temperatures.

The over-all effect of cold work on steel is to increase its strength and hardness and to decrease its ductility (see Chapters 34 and 40). If steel is cold worked in a series of steps, each succeeding deformation increases the hardness until a point is reached where either no further deformation can be effected with the forces that can be exerted by the available cold-working equipment, or the steel will rupture if excessive force is applied in an effort to obtain further deformation. Proper heat treatment will restore the plasticity of the steel so that further cold working can be performed if necessary (see Chapters 34 and 40).

If cold working is carried out in one direction only, as in cold rolling sheets or cold drawing bars or wire, the cold-worked steel is stronger in the direction of working than at right angles to it.

PRINCIPAL COLD-WORKING METHODS

Cold Rolling—Cold working by cold rolling consists of passing unheated, previously hot-rolled bars, sheets or strip (cleaned of scale) through a set of rolls, often many times, until the final size is obtained. Methods and effects of cold rolling wide strip are discussed in detail in Chapter 34.

Cold Drawing—In this process a bar, wire or tube, after being cleaned, is pulled through a die having an opening smaller than the entering piece to reduce the latter to the required size (see Chapter 40).

Cold Extrusion—The cold extrusion of steel is carried out in a manner similar to the hot-extrusion process, with two main exceptions: (1) The steel is at room temperature, and (2) the surface of the piece is treated by some chemical process such as bonderizing to assist in reducing friction between the steel and the container wall and die, in conjunction with special lubricants.

Chapter 20

INGOTS AND THEIR PREPARATION FOR ROLLING

SECTION 1

INGOT CHARACTERISTICS

Ingots—Following completion of the refining operation in the open hearth, Bessemer converter, or electric furnace, the molten steel is poured from the furnace into a ladle. From the ladle, the steel is **teemed** into a series of **molds** of the desired dimensions, where the liquid metal is allowed to solidify in whole or part. These solidified steel castings are called **ingots**. Before rolling begins, however, the ingots must have been allowed to solidify throughout, and the whole body of metal should be of uniform temperature. During natural cooling, these conditions are not fulfilled, because the outside of the ingot, being the part from which the heat is removed most rapidly, is the first to solidify and is cooler than the interior. The molds are stripped from many ingots while their central portion is still so hot as to be in the liquid state. This fact was recognized by early steel workers, so it was originally the custom to strip the molds from ingots as soon as possible, and then place the ingots in a tightly covered hole or pit in the ground, where the heat from the interior of the ingot was conveyed slowly to its relatively colder outside portion by conduction. This sufficed not only to heat the colder ex-

terior part of the ingot, but also to supply heat to the pit which, with careful manipulation, was kept hot enough to maintain ingots at a suitable rolling temperature. This process was called **soaking**, hence the name **soaking pit**. In order to bring the soaking under better control and make it adaptable to varying conditions of operation, means for supplying additional heat were introduced, so that the modern soaking pit is, in reality, a kind of heating furnace; detailed descriptions of soaking pits are given in Chapter 21.

Ingot Characteristics—An ideal ingot would be one free from non-metallic matter, and from all cavities or openings, and of uniform physical structure and chemical composition throughout. Unfortunately, the natural laws that govern the solidification of a liquid metal operate against these requirements, and develop the well-known natural phenomena called **pipe**, **blowholes**, **segregation**, **columnar structure**, and **internal fissures**. Added to these are detrimental occurrences, both incidental and accidental, such as **ingot cracks**, **non-metallic inclusions**, and **scabs**. A brief discussion of these phenomena will follow, but a proper understanding of

FIG. 20—1. Cross-sections (not to scale) of the five principal types of ingot molds. Molds usually are cast from molten pig iron directly from the blast furnace.

FIG. 20-2. Solidification pattern of 32" \times 32" hot-topped big-end-up ingot of killed steel.

pipe, blowholes, and segregation, and the methods for controlling them, requires a brief study of the mechanism of solidification of ingots.

Nature of the Cooling of An Ingot—The ingot molds in common use are tall, box-like containers made of cast iron, weighing usually from one to one and one-half times as much as the ingot they produce. The inside cavity is slightly larger at one end; thus, the ingots taper from one end to the other to make it easier to separate the ingot and mold. As shown in Figure 20-1, this gives rise to two main types of molds—big-end-down and big-end-up. Big-end-down molds are classified as open-top and bottle-top. Big-end-up molds are classified further into open-bottom, solid-bottom and plug-bottom molds. In the last-named type, the interior is constricted at the bottom to a small, circular opening,

closed with a refractory or metal plug before the ingot is poured. In all open-bottom molds, the bottom opening is closed by placing the mold on a cast-iron base called a stool (Figure 20-1).

As molten steel is poured into an ingot mold, the metal next to the mold wall and stool is chilled by contact with the cold surfaces and solidifies on the bottom and sides to form what is called the skin of the ingot. As more and more heat is extracted by the mold, this skin grows in thickness, but, for several reasons, it grows at a rapidly decreasing rate. As the temperature of the inside of the mold approaches that of the outside of the ingot, the rate of heat transfer decreases. Also, in both big-end-down and big-end-up molds, an air gap forms between the ingot and the mold wall because of the contraction of the former and the expansion of the

latter. As solidification progresses the distance between the mold wall and the remaining molten metal increases and the temperature gradient decreases, thereby decreasing the rate of heat transfer.

Also during the solidification process, gases are evolved from the metal to a greater or lesser degree, depending upon the type of steel, as will be discussed later.

Time for Solidification of Ingots—The rate of solidification is affected by the thickness of the mold wall and the design of the mold. Figure 20- 2 shows the idealized solidification pattern of a 32-inch by 32-inch killed-steel ingot, with the lines labeled 20, 40, etc., indicating the limits to which solidification had progressed after a corresponding number of minutes. The location of these lines was established on the basis of data obtained by pouring a series of identical ingots and then dumping one after another at set intervals to pour out the re-

maining liquid steel. The solidified shells were then removed from the molds and split vertically for study and measurement. These were hot-topped ingots of killed steel of the following composition:

Element	(%)
C	0.83
Mn	0.77
P	0.014
S	0.024
Si	0.18
Ni	2.08
Cr	0.15

The relationships for determining the comparative rates of solidification of ingots of various sizes and shapes are quite complex and are outside the scope of this book.

SECTION 2

TYPES OF INGOT STRUCTURES

When molten steel cools to the temperature range in which it begins to solidify, the solubility of the gases dissolved in the metal decreases, and the proportions of gases that can no longer be held in solution are expelled from the metal. Still more important to the present subject, the chemical equilibrium between carbon and oxygen is changed as the temperature falls, and these two elements react to form carbon monoxide that is evolved from the metal during cooling as the system attempts to establish a new equilibrium. The molten steel does not solidify at a precise temperature but over a range of temperature, so that gases evolved from still-liquid portions may be trapped in semi-solid plastic zones to form blowholes.

The various types of ingots—**killed**, **semi-killed**, **capped** and **rimmed**—are dependent for their characteristics upon the extent to which gas evolution is suppressed. Control of gas evolution is effected by controlling the amount of oxygen dissolved in the liquid steel so that the unavoidable reaction between carbon and oxygen will occur only to the desired degree. The amount of oxygen in the steel is controlled to some degree by controlling the characteristics of the slag in the furnace, but chiefly by the addition of deoxidizers to the molten steel in the furnace during the finishing period, in the ladle or in the molds or in all three as required for the particular type of steel being produced.

Figure 20—3 illustrates diagrammatically eight typical

conditions of commercial ingots, cast in identical bottle-top molds, in relation to the degree of suppression of gas evolution. The dotted line indicates the height to which the steel was poured originally in each mold. The ingots range from dead-killed (No. 1) to violently rimming (No. 8). The differences between these structures are the result of the varying amounts of gas evolved by these ingots as they solidified. No. 1, a killed ingot, evolved no gas, the shrinkage which occurred on solidification causing the slightly concave top, and also the large cavities below the top, separated by bridges and together constituting the **pipe**. Dead-killed steels usually are poured in hot-topped molds, which are also usually big-end-up, thus modifying the shape and location of the pipe cavity, but the ingot shown here is better for comparison. No. 2, a typical semi-killed ingot, evolved a slight amount of gas which, however, was sufficient to compensate fully for the shrinkage during solidification, the pipe being replaced by scattered blowholes in the upper half of the ingot. Ferrostatic pressure suppressed the evolution of gas from the lower half of the ingot, and thus prevented formation of blowholes in that zone. The gas pressure was sufficient to bulge upward the solidifying top surface of the ingot.

No. 3 evolved considerably more gas than No. 2. The excess, above that required to compensate for shrinkage, formed **skin** or **honeycomb blowholes** damagingly close to the surface in the upper half of the ingot. The gas

FIG. 20—3. Series of ingot structures.

pressure ruptured the initially frozen top surface of the ingot, forcing liquid steel up through the rupture, where it then froze; this phenomenon is called bleeding.

No. 4 evolved so much gas that the top surface could not even start to solidify. Instead, so many honeycomb blowholes formed damagingly close to the surface, and from top to bottom of the ingot, that the steel rose rapidly in the mold after pouring with a boiling action, called **rimming action**, so that it had to be checked by the application of a metal cap at the top of the mold. No. 5, a typical **capped** ingot evolved still more gas; so much that the strong upward currents along the sides in the upper half of the ingot swept away the gas bubbles that otherwise would have formed blowholes. Even in the lower half of the ingot, the blowholes could not form until gas evolution had moderated somewhat, so that the solid "skin" over the honeycomb was thick enough that the blowholes, in an ingot of this type, seldom would be exposed due to scaling during heating in the soaking pit. In No. 5, owing to fewer honeycomb blowholes being formed than in No. 4, the steel rose less rapidly to the cap at the top of the mold.

No. 6 is a **rimmed** ingot, as are also Nos. 7 and 8. In No. 6, the evolution of gas, while more than for No. 5, was insufficient to keep honeycomb blowhole formation from slightly exceeding shrinkage, so that the top surface of the ingot rose slightly as it froze in from the sides of the mold. In No. 7, a typical rimmed ingot, there was a strong evolution of gas so that honeycomb formation, confined to the lower quarter of the ingot, just about balanced shrinkage, the top surface not rising or falling appreciably as it solidified in to the center. In No. 8, a violently rimming ingot, typical of low-metalloid steel, no honeycomb blowholes could form and the top surface of the ingot fell markedly as solidification proceeded.

These eight ingot structures, representing the four main types of ingots, namely, killed, semi-killed, capped, and rimmed (Nos. 1, 2, 5 and 7, respectively) together with the intermediate or extreme forms (Nos. 3, 4, 6, and 8) are merely selected samples from a continuous series of structures, varying from fully killed to fully rimmed. The gas responsible for this series of structures is a mixture, with carbon monoxide as the chief component. The other gases in the mixture probably are dissolved in the steel, while the carbon monoxide is the result of a chemical reaction taking place about as follows:

Carbon monoxide gas is formed during the cooling of the liquid steel to the solidification temperature range, and during solidification, by reaction between the iron oxide and the carbon dissolved in the steel, according to the equation:

Evolution of the gases is due to several complex, inter-related factors. Simply, however, it may be stated that: (1) At the finishing temperature, the iron oxide and carbon contents of the liquid steel are in equilibrium; as the steel cools, the equilibrium is disturbed, and these two constituents begin to react in an effort to restore a chemical balance. Since cooling is continuous, a new state of equilibrium is not attained, and gas continues to be evolved. (2) The solubility of gases in molten steel is much greater than in solid steel; consequently, most of the gas still in solution in the steel at the time of solidification is ejected from solution in the steel at the time the latter solidifies. As the steel is in a more or less plastic condition at the solidification point, the last gases evolved or liberated may not be able to escape from the body of the metal, and will collect in bubbles as all gases do in making their way out of any liquid.

Since there is sufficient carbon even in low-metalloid steel for a violent evolution of carbon monoxide, it follows that the type of ingot structure will depend chiefly on the iron oxide (FeO) available for the above reaction while the steel is solidifying in the molds. This in turn depends on the carbon content of the steel at tap (the FeO content being greater as the carbon is less) and upon the amount of deoxidizers used.

From the above explanation, it will be understood that types of ingots requiring the evolution of large amounts of gas, such as rimmed or capped ingots, cannot be produced if the carbon content is high (above 0.30 per cent), because the oxygen content would be too low for a strong evolution of gas, but enough for a mild or disturbing influence. Semi-killed and killed ingots can, therefore, be made from such steel by proper additions of substances (deoxidizers) to combine with any unwanted excess of iron oxide. On the other hand, any type of ingot structure can be produced from low-carbon steel, merely by adjusting the amount of deoxidizer used in furnace, ladle, or molds. However, in very low-carbon steels, the excessive amounts of deoxidizer required for the production of killed or semi-killed ingots add to the expense and give rise to objectionable amounts of products of deoxidation, so that there are often practical advantages in making the lower carbon grades rimmed or capped, and the higher carbon grades semi-killed or killed.

Pipe—The shrinkage cavity, or pipe, located in the upper central portion of the ingot, is largest and most deeply located in the two extremes of ingot structure represented by ingots Nos. 1 and 8. Less extreme structures, such as No. 2 (semi-killed) or No. 7 (strongly rimming) exhibit this tendency to a lesser extent, while the product of an ingot of intermediate structure such as No. 5 (capped) will be practically free from pipe after rolling. Big-end-down killed ingots (poured without a hot-top) often have the lower portion of the pipe cavity below the bridges clean enough to be welded satisfactorily during rolling. This is true particularly for the higher carbon steels or where the percentage of reduction during rolling is high, as in the lighter, flat-rolled products. In these cases, a satisfactory yield of sound rolled product often can be obtained without special steps being taken to eliminate pipe. If assurance of complete freedom from pipe is required, it is accomplished best in killed-steel ingots by making them big-end-up, with a hot-top, as shown in Figure 20—4, No. 1.

FIG. 20—4. Types of killed ingots.

1. Big-end-up, hot topped.
2. Big-end-down, hot-topped.
3. Big-end-up, not hot-topped.
4. Big-end down, not hot-topped.

The refractory material with which the hot top is constructed or lined absorbs heat less rapidly than the cast iron of the mold so that the top of the ingot remains liquid until after the remainder of the ingot has solidified, thus furnishing an overlying pool of liquid steel which feeds down into the lower portions of the ingot to overcome the shrinkage due to solidification. By using big-end-up molds, this feeding is made still more effective.

Blowholes—In all except killed ingots, the evolution of gas produces cavities of roughly cylindrical shape (skin or honeycomb blowholes) or spherical shape (located deeper in the ingot). Except for the ones located within several inches of the top of the ingot, such blowholes tend to have interiors clean enough to weld easily and completely during rolling, unless they extend to the surface of the ingot, or lie at such shallow depth beneath the surface that they become exposed by oxidation of the surface of the ingot during heating in the soaking pits. In both such cases their interiors become oxidized and they will not weld, resulting in numerous seams in the rolled product. Properly made ingots, therefore, will have gas evolution during solidification so controlled that there will be a skin of adequate thickness over those blowholes closest to the surface. The fact that blowholes serve a useful purpose in diminishing or preventing the formation of pipe already has been mentioned.

Segregation—When a complex material like liquid steel undergoes solidification, the first parts of the ingot to become solid are purer than the original liquid steel. This is called **negative segregation** and means that such solid steel is lower in carbon, manganese, phosphorus, sulphur, and other elements than the liquid steel from which it solidified. As a result of this action, the remaining liquid steel becomes increasingly enriched in these elements, so that the tendency of the solidifying steel to be purer than the original liquid steel is after a time arrested and then reversed. In this way the last steel to solidify contains notably greater amounts of these elements. This is **positive segregation**, and occurs to the greatest extent in the very last steel to solidify. This is in the top central part of the ingot, and, in killed steels, is adjacent to and just below the pipe cavity.

Some elements segregate to a greater extent than others. Sulphur is the worst offender in this regard, followed by phosphorus and carbon, while manganese and silicon show little tendency to segregate.

The tendency of the elements to segregate while solidifying increases with the time required for solidification, so that large ingots tend to segregate more than smaller ones. Still more effective in promoting segregation is any movement of the liquid steel relative to the solidifying surface. Killed steel in general, therefore, is least segregated. The slight stirring of the liquid steel caused by the evolution of gas in semi-killed steel produces a corresponding slight increase in segregation, and the rimming action of capped steel prior to capping produces a thin rim zone exhibiting negative segregation, the thickness of which depends on the time elapsing between pouring the ingot and sealing the top with a metal cap. After sealing, the evolution of gas is mechanically suppressed, and the remainder of the steel solidifies after the manner of a semi-killed ingot. However, since the thin rim layer is strongly segregated negatively, the positive segregation of the center of the ingot is somewhat greater than for a semi-killed ingot. Rimmed ingots are the most segregated of all, as the prolonged rimming action produces a thick rimmed zone of negative segregation. Since the rim zone can be almost half the volume of an ingot, it follows that the

core zone, which solidifies after the fashion of a semi-killed ingot when the top of the ingot finally freezes over, exhibits strong positive segregation. The boundary between rim and core zones is relatively sharp, and these zones are so different as regards composition and appearance after etching as to resemble different steels.

There are certain other special aspects of segregation in killed steel which are of interest, but can only be mentioned here; these include **axial porosity** (associated with the "V segregate" along the central axis of an ingot) and **ingot pattern** which may be due to the ingot being disturbed while solidifying, or to the type of segregation called "inverted V segregate."

Columnar Structure—Steel after solidification is a crystalline material, and the first molten metal to strike against the comparatively cold mold wall freezes rapidly into a structure characterized by small and randomly oriented crystals, which occasionally may persist (in small ingots) to the center of an ingot, and which tend to become larger as they approach the center of the ingot. Usually, however, this initial zone of randomly oriented crystals soon gives way to large crystals called **dendrites**, characterized by a branching structure developed as the crystals "grow." The principal direction of growth is perpendicular to the mold wall, so that all dendrites so formed have essentially the same orientation. If growth of the individual dendrites occurs principally along their longitudinal axes perpendicular to the surfaces of the ingot, these large elongated crystals, under suitable circumstances, may extend all the way to the center of the ingot. An ingot having a preponderance of these large elongated crystals is referred to as possessing a **columnar structure** and, if the structure is exaggerated in extent, it is referred to as **ingotism**. Ingots exhibiting ingotism tend to crack excessively during rolling unless light drafts are employed for the first few passes in the rolls. In most ingots, however, columnar structure gives way, toward the center of the ingot, to rather large, equiaxed, randomly oriented crystals, which also are dendritic in character. The relative proportion of columnar and equiaxed dendritic crystallization appears to be dependent upon many variables, among which are composition of the steel, mold temperature, pouring temperature and gas content of the steel.

Internal Fissures—Tensile stresses in the interior of an ingot, arising during cooling, heating, or rolling of the piece, may produce **internal fissures** or **internal bursts**, sometimes of a very large size. If these do not extend to the surface they will weld completely during the rolling operation, provided the amount of hot work (percentage of reduction) is sufficient.

✓ **Ingot Cracks**—If the fractures produced by tensile stresses extend to the surface or originate at it, they produce the visible defects called **ingot cracks**. Such exposed cracks become oxidized, producing large seams in the rolled product. This type of defect receives more detailed attention in Chapter 26 on steel conditioning.

Non-Metallic Inclusions—All steel ingots contain more or less non-metallic matter, consisting almost exclusively of oxides, with lesser amounts of sulphides, in various combinations and mixtures with each other. They are derived chiefly from the oxidizing reactions of the refining process and the deoxidizing materials added to the steel in the furnace, ladle, or molds. Some result from erosion of ladle refractories during pouring. They were supposed formerly to be admixed furnace slag, but this material now is recognized as only a minor source of these inclusions.

Scabs—In top-poured ingots the liquid steel, falling

from a height upon the stool or the bottom of the mold, splashes violently against the lower part of the mold walls. Many of these splashes adhere and solidify, forming a continuous layer on the bottom foot or two of the mold walls. Above this point the adhering splashes rapidly decrease in number and become discontinuous. This splashing diminishes as a pool of liquid metal forms in the bottom of the mold. The adhering splashes cool rapidly, and their surfaces oxidize. If the cooling and oxidation have progressed too far by the time the liquid steel in the mold rises past them, they will not be incorporated into the ingot, but remain as adhering and imperfectly bonded scabs on the surfaces of the ingot which, if thin, may be oxidized away in the soaking-pit operations. If thick, they produce a similar defect on the rolled product, as discussed in Chapter 26. As the continuous layer of splashes cools, its upper edges tend to bend inward and, as the rising liquid steel overflows them, to become enfolded. Horizontal ingot cracks, called **butt cracks** often occur below and parallel to such folds, and the folds themselves can produce surface laminations or seams in the rolled product.

The defects associated with pouring splashes can be reduced by filling the mold more rapidly, so that the rising level of liquid steel covers the splashes before they can cool and oxidize. This is done by using larger or multiple nozzles, which practice, however, gives rise to various mechanical difficulties if carried to extremes.

There is also a danger, especially with higher pouring temperatures, that high pouring rates will lead to greater ingot cracking.

Bottom pouring also will minimize this defect, since the molten steel enters the mold from a runner through an opening in the mold bottom and there is little splashing as compared with top-pouring practice.

Mold Coatings—Another method of improving ingot surface is to coat the inside of the molds with a substance which tends to repel splashes. Many substances have been proposed or tried for this purpose. Among these few are tar, powdered pitch, gilsonite, graphite, and aluminum paint. The last often is used on molds for killed steel of the higher-alloy grades. Tar is probably the most effective splash repellent, but, if used under unsuitable conditions, gives rise to annoying fumes. Powdered pitch has some of the effectiveness of tar, and the fumes are less objectionable. Gilsonite approaches tar in effectiveness and produces a minimum of fumes when properly applied. With carbonaceous coatings, such as tar, powdered pitch, or gilsonite, the temperature of the molds at the time they are coated is important. If they are too hot, the coating is decomposed and the residual charred film has no beneficial effect. If they are too cold, the coating is extremely heavy, and the excessive amount of gas accompanying its decomposition by the liquid steel gives rise to subsurface blowholes in the ingot.

SECTION 3

CONTROL OF INGOT STRUCTURE

Steelmaking and Deoxidation Practices—The previous discussion has shown that the final structure of an ingot is determined almost entirely by the degree to which the steel from which it was cast has been deoxidized. The several types of steel require different steelmaking and deoxidation practices, which are described briefly in the following summary of the principal steps involved.

Rimmed Steels—For rimmed steels, proper rimming action in the molds has been described as necessary to produce the surface conditions and ingot structure desired. Slag control is aimed at adjusting the lime-silica ratio and iron-oxide content of the slag to give the desired level of oxidation of the bath of metal when the heat is ready to tap. The exact procedures followed depend on whether the steel has a carbon content in the higher ranges (0.12 to 0.15 per cent), in the lower ranges (0.06 to 0.10 per cent), or under 0.06 per cent.

Rimmed steel usually is tapped without deoxidizing additions to the furnace and with only small additions in the ladle, in order to have sufficient oxygen present to give the desired gas evolution when reacting in the mold with carbon. This type of steel, when properly made, has a minimum of pipe and a good surface though it is subject to segregation. When the metal in the ingot mold begins to solidify, there is a brisk evolution of gas resulting in an outer ingot skin of relatively clean metal. For many applications, particularly where the surface of the product is important, this steel is used to a considerable extent.

The thickness of this outer skin and the absence of blow holes and oxides from it depends on the skill of the steelmakers. When the temperature and the oxygen level of the steel, as it is poured from the ladle, are within the most desirable limits, the desired evolution of carbon monoxide from the steel as poured into the molds is obtained by the reaction of oxygen in the steel with carbon, and to finally control and obtain the most

effective rimming action, the very careful use of shot aluminum, in small quantities, is necessary as the ingots are poured. The amount to be added is determined in pouring the first few ingots. The largest proportion of this steel has a carbon content of under 0.15 per cent. Ferromanganese may be added to the furnace before tapping or in the ladle, but it is usual to make the addition in the ladle. Aluminum, ferrotitanium or other deoxidizers in small amounts may be added in the ladle, if needed. If the steel is deoxidized to too great an extent up to the point where the pouring of ingots begins, the rimming action will be incomplete because the evolution of gas is too small in volume and too slow in starting its evolution.

Capped steel practice is a variation of rimmed practice. The steel is poured into big-end-down bottle top molds in which the constricted top or mouth of the mold facilitates the capping operation. The rimming action is allowed to begin normally but is then terminated at the end of a minute or more by sealing the mold with a steel or cast-iron cap. The addition of a small amount of shot aluminum during pouring insures that the steel rises to press against the cap. The oxygen level of the steel as poured into the mold is preferred to be not more, and possibly slightly less, than the desired level for rimmed steel. The product is an ingot with a thin rim which is relatively free of blow holes and with segregation less than is usual for a rimmed ingot of the same volume. On steels (other than killed or semi-killed) of higher carbon content than 0.15 per cent, this method is used to advantage. Steel of this type is applied on sheet, strip, skelp, tin plate, wire, and bars.

Semikilled steel is deoxidized less than killed steel and there is oxygen still present in the molten steel to react with carbon and to form gas after the steel is poured into the molds. The steel finds wide application in structural shapes, plates and merchant bar. Structural

steel is generally in the range of 0.15 to 0.30 per cent carbon, because this provides appropriate strength, and such steel is generally semikilled. The usual practice is to bring the carbon content of the bath to the desired level for tapping. The manganese may be added as ferromanganese to furnace or ladle, or divided. If large amounts are necessary, at least part should be added to the furnace. Carbon, ferrosilicon, ferrotitanium and aluminum may be added to the ladle. It is usual to accomplish most of the deoxidation in the ladle, so that only a few ounces per ton of aluminum will be required in the mold.

Killed Steel—The term "killed" indicates that the steel has been deoxidized sufficiently for the metal to lie perfectly quiet when poured into an ingot mold. There is no evolution of gas and the top surface of the ingot solidifies with relative rapidity. Killed steel generally is used when a homogeneous structure is required. Alloy steels, forging and carburizing steels are of this type, when the essential quality is soundness (freedom from blow holes and segregation). In general, all steels with more than 0.30 per cent carbon content are killed. In making killed steel, the usual practice is to "catch the heat coming down;" that is, to lower the carbon content of the bath to the desired level and then either block the heat (deoxidize it) by adding high-silicon pig iron (15 to 25 per cent silicon), silicomanganese, or spiegel, or to tap the heat and depend upon ladle deoxidation.

Blocking lowers the oxygen content of the liquid metal to prevent further oxidation of carbon; it also serves to protect alloying elements which are susceptible to oxidation and consequently are added after the heat has been blocked.

At the final part of the finishing period, the carbon will have been worked down until it is at a level which

in best practice is such as to bring the steel within the required range in tapping and pouring. The phosphorus and sulphur should be below the specified maximum, the manganese usually will be below the minimum required, and the bath temperature should be proper for the composition and grade of the steel being produced. The steel is then ready for whatever ferroalloys need to be added (ferrosilicon, ferromanganese, other alloys).

The decision as to whether a ferroalloy addition is made to the furnace or to the ladle is determined largely by the susceptibility of the ferroalloy to oxidation. Manganese may be added to the furnace or to the ladle, or divided between them, but the additions to the ladle must not be so large as to chill the metal too much. The furnace additions are chosen and the timing of addition set so that the maximum elimination of the solid oxides formed will take place by floating up through the metal to the slag before the metal is tapped from the furnace. After tapping, other deoxidizing additions may be added to the steel as it runs into the ladle. These complete the deoxidation to the desired degree up to the pouring into molds. These ladle additions are usually ferrosilicon, aluminum or other special alloys (calcium-silicon is an example) containing elements which have a strong affinity for oxygen. Additions containing such elements as manganese or silicon furnish part of the elements required to meet the specified chemical composition. Additions of deoxidizers to the molds may be made, depending on the type of steel.

In producing certain extra-deep-drawing steels, a low-carbon steel (under 0.10 per cent carbon) is killed, usually with a substantial amount of aluminum, added in the ladle, molds or both.

A large proportion of killed steel is poured into hot topped, big-end-up molds.

SECTION 4

HEATING INGOTS FOR ROLLING

The main function of soaking pits (see Chapter 21) is to bring ingots to a uniform temperature suitable for rolling and to do this without damage to the ingots themselves. Between the time the ingots are poured and the moment when they are ready for rolling, the various manipulations to which they may be subjected are all for the purpose of attaining one or more of the following three objectives:

1. **To Insure Solidification of the Ingot**—Ingots of some killed steels must be allowed to become completely solid before being moved from the pouring platform. For some other killed steels, the ingots can be moved away from the pouring platform within a short interval after pouring, say 20 minutes, but not thereafter until completely solid. For all other types of steel, there are usually no holding requirements from the standpoint of internal quality. Such ingots may, therefore, be moved, stripped, and charged into the soaking pits as soon as solidification has progressed far enough to enable them to endure the stresses involved in such handling.

To save time and fuel, therefore, ingots of many grades of steel are charged soon after pouring, when their interiors are still largely molten. If the heating of such ingots should be started immediately after charging, solidification would be retarded to such an extent that the center portions of the ingots would still be liquid, or at least in the mushy stage of solidification, when the remainders of the ingots were ready to roll. In such cases, therefore, the pits may be dampered for

a period after the ingots are charged; that is, the fuel is shut off and the connection to the waste-gas flue is closed, the latter to prevent natural draft from causing cold air to pass through the pit. During such a dampering period, the exterior portions of the ingots do not receive much heat from the pit, while the centers of the ingots continue to solidify by transferring heat to the exterior surfaces. The duration of such dampering periods should, of course, increase with increasing ingot size, especially as determined by the least dimension (thickness), and decrease with increasing "track time," i.e., the interval between finish pour and charge.

An alternative method of insuring complete solidification of the ingots after charging and before rolling is to set up minimum track times, which increase with increasing ingot thicknesses.

2. **To Avoid Rupturing the Surfaces or Interiors of Ingots**—Ingots of some grades of steel are notoriously more sensitive to thermal shock than those of other grades and can, therefore, be damaged or ruined by cracks or internal bursts if cooled or heated at too rapid a rate. This sensitivity increases with ingot size, degree of killing, carbon content, and metalloid or alloy content. Thermal shock by cooling may occur between pouring the ingots and charging them into the pits, especially in the interval between stripping and charging.

In certain grades of steel, such as high-sulphur screw stock, it is advisable to make the time between pour and charge, and especially the time between strip and

charge, as short as possible. This particular type of sensitivity perhaps may be due to something else than simple thermal shock, as, for example, the formation of an intercrystalline precipitate within a critical temperature range. If the charging of such steels is to be delayed too long, it may be better to allow the ingots to cool further in the molds before stripping, charging, and reheating.

Thermal shock by heating may occur if ingots are charged into pits which are much hotter than the ingots or if, after charging, the ingots are heated too rapidly. The more sensitive the grade of steel, and the colder the ingots at the time of charging, the more elaborate must be the precautions against such thermal shock. For example, with large cold alloy ingots, it may be necessary to cool the pits until they are not hotter than 800° F, then, after charging the ingots, leave the pit uncovered for some definite period, then cover and let stand for another period, after which firing is begun at a minimum rate, the heat input being controlled carefully and stepped up very gradually.

3. To Bring All Parts of the Ingots to the Desired Temperature—The temperature at which ingots properly heated for rolling are withdrawn from the soaking pit is called the **drawing temperature**. The heating of ingots to this temperature may be considered as taking place in two successive steps, although, for small ingots charged quite hot, the second step occurs so nearly simultaneously with the first step that its existence is not so obvious.

a. Heating the Exterior Portions of the Ingots to Drawing Temperature—To achieve this first result, the pits are fired as rapidly as is safe, having due regard to avoiding thermal shock to the ingots, and to avoid any **burning** of the ingots (see below). Depending upon the type of pits, heat input is controlled by visual observation of the surfaces of the ingots, or by thermocouples recording pit temperatures. These latter usually are arranged to proportion, or at least to regulate, heat input in accordance with pit temperatures, the controls being set to prevent the pits from exceeding a predetermined temperature. This temperature limit has been determined by previous experience to result in the desired drawing temperature.

b. Heating the Interior Portions of the Ingots to Drawing Temperature—A portion of this second result is, of course, being achieved while the exteriors of the ingots are being heated to drawing temperature, and the remainder of this result is secured after the

exteriors of the ingots have reached drawing temperatures. This is accomplished by reducing the heat input (in automatically controlled pits) until it is just sufficient to maintain the exteriors of the ingots at drawing temperature. The heat input at this stage is, therefore, only that required to offset heat losses from the pit and the heat absorbed by the interiors of the ingots. In manually fired pits, fuel input can be reduced by hand control during this soaking period, or an approximation to this controlled reduction of heat input can be secured by alternately firing and dampering the pits for short periods of time.

Since the temperatures of the interiors of the ingots cannot be measured, past experience is the only guide as to the time required to "soak out" the centers of the ingots, taking into account their temperature at the time of charging, their size, and their thermal conductivity.

"Burning" of Ingots—If ingots are heated to excessive temperatures, the surface scale may melt and run. Such ingots are said to be **washed**. If the areas of melted scale on ingots are small, due to localized flame impingement, the ingots are said to be **port marked**. In addition to these effects, excessive pit temperatures can produce the damaging effect called **burning**. This is a complex phenomenon, which can occur at temperatures below the solidus of the steel being heated. The low-carbon grades of steel are almost immune to this trouble, which becomes an increasing hazard as the carbon content of the steel increases, particularly above 0.30 per cent. It is a penetration of iron oxide, usually in combination with iron sulphide, between the grain boundaries at and near the surface of the ingot. It results in scabby, crumbled surfaces on the rolled products (see Chapter 26).

Burning can be avoided by careful control of the temperatures attained by the surfaces of the ingots.

Overheating of Killed and Semi-Killed Non-Hot-Topped Ingots—In these two kinds of ingots, the yield of sound rolled product depends upon the extent to which pipe cavities are welded by the rolling operation. If the top portions of the ingots are heated to too high a temperature, the pipe cavities will not weld successfully. Apparently, the high temperature liquefies non-metallic matter which is present on or near the tops of the ingots, and this then finds its way down into the pipe cavities. Cold ingots particularly are subject to this trouble, and special care in heating is required to minimize pipe rejections.

Chapter 21

CONSTRUCTION AND OPERATION OF HEATING FACILITIES

SECTION 1

PRINCIPLES OF FURNACE DESIGN

Objectives and General Metallurgical Requirements—

A heating furnace is utilized to raise the temperature of steel for hot working (shaping) and for heat treating. Heating furnaces may be divided into three general classes:

1. Soaking-pit furnaces
2. Reheating furnaces
3. Heat-treating furnaces

The function of soaking pits and reheating furnaces is to raise the temperature of steel in the course of processing until it is sufficiently hot to be plastic enough for economic reduction by rolling or forging to the desired section. The function of heat-treating furnaces is to heat the steel to some specific temperature for the purpose of obtaining the desired mechanical properties, which may be developed either by: (a) regulating the speed of cooling of the steel in the furnace; (b) by removing the hot steel from the furnace and permitting it to cool in still or agitated air; or (c) immersing the work directly from the furnace into some liquid to cool it suddenly and thus develop maximum hardness after which, usually, the hardened steel is tempered by further heat treatment.

Heating furnaces must be constructed of suitable materials to withstand the effects of the temperature levels at which they must operate. They must be provided with charging facilities which are adequate for the material size and handling rate, and with the proper means for heating the steel at the specified production rate. From the metallurgical standpoint, all three types of furnaces must be constructed to heat the steel uniformly and, by suitable temperature and combustion control instrumentation, hold it at the desired temperature for a specified length of time. Heat-treating furnaces, in addition, may have to be designed to cool at controlled rates to a predetermined level, and be provided further, in many cases, with extra equipment by which special requirements, such as the control of furnace atmosphere for developing or maintaining the desired surface condition of the steel, may be met.

Basic Elements of Furnaces—There are many different designs for each of the three general furnace classes noted above, but each design (exclusive of salt-bath or lead-bath furnaces, which are discussed in detail in Section 4 of this chapter) consists of certain common parts, as:

1. The heating chamber; an enclosure to contain the material and retain heat.
2. A hearth or support in the furnace for carrying the charge.

3. Facilities for the development of heat to raise and maintain furnace temperature.
4. Means for the distribution of heat and the removal of spent gases from the furnace.
5. Means for the introduction of work to be heated and removal of heated stock.

The enclosure to contain the material and heat generally is called the furnace proper. It usually is constructed of refractory material, although furnaces for operation at relatively low temperatures may be fabricated exclusively of steel. The furnace hearth or support for the charged material also may be constructed either of refractory or metallic material. In high-temperature furnaces, metallic supports generally are water cooled. Furnace hearths are constructed to permit the charge either to remain in a fixed position in the furnace or to be moved during the heating process. An example of the first type of hearth is the conventional batch-type or "in-and-out" furnace. Examples of the second general type are found in roller-hearth furnaces in which the material moves as the series of rollers that constitute the hearth rotate, and in continuous furnaces in which a continuous line of material is pushed over skids. The combustion of fuel usually is employed to develop the required furnace temperature, but the conversion of electrical energy into heat is used also in some important heat-treating furnace installations. The circulation of heat in the majority of furnaces is accomplished by natural convection and stack draft; in others, by forced circulation.

Facilities for the introduction and removal of heated stock vary with the type and size of furnace, the size and shape of the stock to be handled, and the general layout of the furnace and auxiliary facilities. Roller tables, conveyors, charging machines, overhead cranes, furnace pushers and pinch rolls are the principal kinds of equipment used for this service.

Furnace Size and Capacity—The size of a heating furnace usually is described by its hearth area. The hearth areas of the various types of the three general furnace classes differ greatly. Soaking pits may have a hearth area of from 10 sq. ft. to something over 300 sq. ft. Reheating furnaces may have hearths ranging in area from only a few square feet, as in a small forge furnace, to over 2000 sq. ft. in large, continuous slab-heating furnaces. Heat-treating furnace hearths vary in size from the laboratory type of furnace of only a few square feet to areas of 1600 sq. ft. or more found in some of the larger continuous normalizing or annealing furnaces. The productive capacity of a heating furnace often is related to its hearth area, and figures of from

FIG. 21-1. Normal average time for heating various sizes of square mild-steel (low-carbon) and medium-carbon steel billets from room temperature to rolling temperature of 2250°F.

2 pounds to 250 pounds per sq. ft. of hearth area per hour are quoted for the various types. The low rate may apply for some conditions in heat treating steel and the high rate to pit furnaces when heating already hot ingots to a higher temperature. The capacity of a furnace is determined primarily by the area of the surface of the piece to be heated which is exposed to the furnace temperature, and the shape, thickness and composition of the material, its temperature and that of the furnace, and the emissivity of the heat source and of the material to be heated (e.g., surface-ground or machined stainless steel). The desired rate of heating is regulated by manually or automatically controlling the rate of heat input to the furnace.

High-carbon steels and heat-resisting alloys require longer heating cycles to attain uniformity of heating at the same temperature levels, as compared to low-carbon steels. Selection of the time required for properly heating various grades and sizes of steel is based largely on experience with given furnaces heating specific types of products. Figure 21-1 shows the normal time for heating various sizes of cold mild steel and medium-carbon steel blooms and square billets to rolling temperature. The heating time for high-carbon steel is about one-third longer and for heat-resisting grades about twice that shown.

The flow of heat through a thick body of steel is relatively slow compared to surface absorption in high temperature furnaces and, therefore, caution must be exercised in regulating the supply of heat to prevent the surface from "sweating" (partial melting) while bringing the temperature inside the material up to the required level. Figure 21-2 shows the average rate of heat absorption for an entire cycle as generally practiced in heating mild, or medium-carbon grades of steel from atmospheric to rolling temperature. During the early stages of the heating cycle, the heat-transfer rates are considerably above the average shown, while during the latter part of the cycle the rate is very low. In heat treating steel, considerably lower average heat-transfer rates are practiced than those shown in Figure 21-2.

Furnace Type and Shape—There are many types of each of the three general classes of heating furnaces. The selection of type is determined by its suitability for heating economically particular grades, shapes and sizes of the material at the rate and to the temperature level desired. For instance, batch-type furnaces are especially suitable for heating blooms of mixed sizes and lengths in thicknesses over 8 inches; continuous furnaces are used for heating slabs or billets for large orders of uniform length and thickness, and car-bottom furnaces are used for annealing miscellaneous shapes and sizes. The general shape of a furnace depends upon a number of factors, such as capacity desired, space available, auxiliary equipment and metallurgical requirements in heating. Refinements in furnace lines depend within rather wide limits on the kind of fuel used and on the grade and size of steel to be heated. The desired combustion space, temperature level requirements, uniformity of heating and fuel flow are major considerations in furnace design.

Thermal Efficiency—The thermal efficiency of heating furnaces varies considerably because of differences in the temperature level of the heated stock and of the charged material, in the provision of heat recovery equipment such as regenerators and recuperators, in furnace insulation, in operating schedules, and in heating requirements. To cover the full range of all common types of heating furnaces, the thermal efficiency may fall anywhere between 5 per cent and 60 per cent. Large production-line furnaces, such as continuous furnaces equipped with recuperators and insulation, generally give 30 per cent to 40 per cent thermal efficiency over an average month's period of operation. Small shop furnaces, poorly loaded, with no insulation or heat-recovery facilities, have low thermal efficiency. The heat requirement per ton of heated product from heating furnaces for the production line varies from 300,000 to 3,000,000 Btu. The lower figure is obtained when heating hot steel, the higher one with poorly-loaded furnaces heating cold steel.

The sensible heat lost in stack gases is the principal source of heat loss in a fuel-fired furnace. Other losses include the heat loss by conduction through furnace walls, hearth and roof; radiation through furnace openings and from the outer surface of the furnace proper;

FIG. 21-2. Curve showing average rate at which heat is absorbed during an entire heating cycle by mild-steel and medium-carbon steel in heating from room temperature to rolling temperature in reheating furnaces.

the heat absorbed by water-cooled furnace parts; and the latent heat and unburned combustibles in stack gases.

In Chapter 3, dealing with fuels, the means employed for reducing furnace losses and the salvage of heat in waste gases already have been reviewed. Regenerators are provided usually for batch furnaces operated at high-temperature levels. They provide, in addition to heat salvage, a reservoir of potential heat for equalizing the temperature of steel during the soaking period. Ordinarily, in regenerative batch-type furnaces, the actual time for firing fuel amounts to only 50 per cent of the total time from charge to charge; the balance of time is taken up by charging, drawing and soaking. Firing in regenerative furnaces is usually at a constant rate with intervals of soaking, which occur more frequently as the charge approaches rolling temperature.

The heat stored in thick furnace walls of ordinary firebrick at high hot-face temperatures is considerable. When the so-called flywheel effect of hot walls and regenerators is not desirable, such as in furnaces which occasionally must be cooled as quickly as possible to lower than usual operating temperatures to receive special alloy or high-carbon heats, a material saving in production, fuel economy and maintenance can be effected by constructing the walls and roof of insulating rather than of regular firebrick.

Recuperators generally are supplied for high-temperature heating with continuous reheating furnaces and soaking pits, and in some instances for batch-type furnaces. They are more desirable than regenerators when the control of atmosphere and a constant flow of fuel into the furnace is important. They usually are designed to provide a lower preheat temperature than is obtainable with regenerators.

Materials of Construction—The temperature level carried in various parts of the furnace determines the kind and grade of construction materials that must be used. The hot end of continuous and regenerative batch furnaces, which employ burners or a fuel developing intensive combustion, may reach temperatures up to 2800° F. For this level, it is customary to construct the walls and roof of first-quality or super-duty firebrick and to water-cool any metallic parts which are exposed to high temperature. In high-temperature furnaces, there are applications for the use of special refractories.

Hearths are constructed usually of refractories resistant to abrasion, slag attack or adherence to the steel being heated. Door jambs are made of refractories with non-spalling characteristics. Pier walls, such as those used in top- and bottom-fired continuous furnaces, use refractories with good hot-load-bearing properties. In pit furnaces, slag-resistant refractories are used in the lower wall areas to combat chemical attack by cinder.

Flue temperatures, especially following recuperators or regenerators, seldom exceed 1600° F, and for this application second-quality firebrick generally is used. Cast iron or heat-resisting steel is used for constructing dampers up to this temperature level; in flues subject to higher temperatures, the dampers are water-cooled. Annealing and normalizing furnaces seldom are operated in excess of 1700° F, and tempering or drawing furnaces normally operate at even lower temperatures. In these furnace types, insulating firebrick is used generally, especially when the operations are intermittent. In many heat-treating furnaces which require a careful control of the furnace atmosphere, particularly in those where special inert gas is used for this purpose, the heating chamber proper consists of a leakproof muffle of heat-resisting steel in which the work is sealed and surrounded by the controlled atmosphere, while heat is supplied to the outside of the muffle and transferred to the work through the muffle walls.

Besides the refractories and metallic parts directly exposed to internal furnace temperature, many furnaces contain a number of other essential parts which must be given careful consideration due to the temperatures to which they will be subjected. Cast-iron doors and door frames usually are lined with refractory material for protection; roof hangers are cast of heat-resisting metal; furnace casings and steelwork usually are constructed of ordinary grades of carbon steel; regenerators generally utilize refractories; recuperators are constructed either of refractory or metal, depending upon the temperature level at which they are to operate. Various grades of insulating material are used, dependent upon load, location and temperature level. Insulation for reheating-furnace walls, roof and hearth, not only provides a saving in fuel but also aids in maintaining a uniform temperature within the furnace, reduces stresses in furnace brick and steelwork, and improves working conditions around the furnaces.

SECTION 2

SOAKING-PIT FURNACES

Introductory—The modern soaking pit has been developed to provide uniform heating of ingots to the desired temperature with a minimum of over-heating of the surface. In most modern designs, this is accomplished with automatic controls. The normal range for heating ingots is between 2150° F and 2450° F. The proper temperature level varies with grades of steel and sizes of ingots and characteristics of the rolling mill. Low-speed mills with many passes require the higher level of heating for certain grades of steel. Soaking pits serve the dual function of heating and acting as a reservoir to correct irregularities in the flow of ingots between the steelmelting shop and the primary rolling mills. Briefly, soaking pits are deep chambers, or furnaces, of square, rectangular or circular shape, into which ingots are placed in an upright position through an opening at the top (Figure 21—3). A removable cover closes the pit opening. A series of pits, installed usually in rows, are placed under cover of a building adjacent

to the entering side of the blooming or slabbing mill to be served. The top of the pit is usually several feet above ground level. The pits are spanned by one or more electrically operated traveling cranes equipped with a traveling hoist for charging the ingots into the pits and for lifting them out as they are needed by the mill. The lower end of this hoist is provided with adjustable tongs, by which an ingot may be grasped at the top and moved vertically a distance greater than the depth of the pit. This crane is used to transfer the ingots to the pits from the cars on which they were brought from the stripper, moving on tracks usually located along the side of the pits. For heated ingots, a pot car or ingot buggy is provided, which usually is propelled electrically along a track leading to the primary-mill tables, upon which it automatically deposits the ingots.

Types of Soaking-Pit Furnaces—There are several modern designs of soaking pits. Each design has special heating characteristics. The oldest of the modern types

FIG. 21-3. Schematic cross-section through a soaking-pit furnace building. (Courtesy, Amsler-Morton Company.)

is the regenerative pit. In this type, the ingots are heated by alternately burning the gas through a port in the pit wall on one side, permitting the products of combustion to pass across the pit and out through the regenerator flues and stack to the atmosphere. The air, after each reversal, is passed through the hot regenerators to provide preheat for combustion of the fuel. If fuels of high calorific value, e.g., fuel oil, natural gas, or coke-oven gas are burned, they are introduced either through pipes in the top of the checker chamber and directed toward the bridgwall, or through a well in the checker brickwork adjacent to the port bridgwall. In some installations, particularly when cold blast-furnace gas is used, burners have been installed in the rear walls of the checker chambers. Since the ports are located in the endwalls of the pit, the ingots are exposed to conditions of unequal heating on their opposite sides. To equalize ingot temperature, the practice of firing and dampering is generally followed. This practice provides uniformly-heated steel at a relatively-fast heating rate, but generally causes high scale losses, due to the flow of air through openings in the flues or checker chambers into the pit proper and out through holes in the pit cover or through faulty cover seals each time the pit is dampered. Corrective measures have been applied in modern regenerative pits by careful sealing of the checker-chamber brickwork and the installation of self-sealing covers. Difficulties from scaling are not confined only to regenerative-fired pits, but also may be met in recuperative-fired pits if there are leaks in the recuperators.

One of the first major steps towards improvement in pit-furnace design was to provide sufficient space for the combustion of fuel. Pits of a continuous-fired design, known as one-way fired pits (Figure 21-4), equipped with recuperators, were designed to provide combustion space above the ingots, where the space available

for combustion was not affected by ingot coverage. "Ingot coverage" is a term used to denote the tonnage or number of ingots charged into a pit. Instead of the horizontal flow of gases through the pit as in the regenerative type, the flow in this type is vertical in accordance with hydrostatic principles.

In another type, designated as the bottom center-fired or vertically-fired pit, a section of which is shown in

FIG. 21-4. Diagrammatic elevation and plan view illustrating principle of continuous firing and flow of hot gases in a "one-way fired" soaking pit. Hot gases from outlet ports pass to recuperators (not indicated).

FIG. 21-5. Schematic elevation and plan view of a "vertically-fired" soaking pit, with the burner opening in the center of the pit bottom. (Courtesy, Amsler-Morton Company.)

Figure 21-5, the fuel is fired vertically through a port, centrally located in the bottom of the pit, around which the ingots are placed. As the products of combustion rise in the combustion zone, some of the spent gases which are moving downward around the ingots and next to the furnace walls are drawn into this inner column of hot rising gases, and the resulting good circulation

equalizes furnace temperature. Flues are located at the bottom corners of opposite sides of the pit to remove products of combustion and to aid in heat distribution. This design was introduced with recuperators and a full quota of controls for carrying out program heating. Adequate provision for combustion of fuel and careful sizing of pits, of nearly square shape, to suit loading conditions are incorporated in the design.

Another type, which is called the **circular pit** (Figure 21-6) employs tangential firing from a series of recessed burners located in the lower periphery of inclined side walls, to permit unusually long travel of the gases and to induce recirculation of the spent gases before they leave the pits through a centrally-located exit port at the bottom of the pit. This design utilizes a method for tempering the flame and securing uniform pit temperatures through gas circulation. These pits normally are fired with a high-calorific fuel and cold air in premix or nozzle-mix type burners to obtain complete combustion of the fuel before the gases come in contact with the ingots.

Still another pit is a refinement of the continuous-fired pit furnace, known as the **bottom two-way fired pit** (Figure 21-7). In this design the pits are fired by burners located in opposite endwalls about two feet above the bottom of the pit. The waste-gas ports are located in the same endwalls at each of the four pit corners and the gases on each end go directly to a recuperator. Combustion of the fuel takes place in a centrally located aisle, at the sides of which the ingots are placed. The method of firing and the position of the burners and waste-gas ports provide turbulence to the flow of gases in the pit, and results in improved heating of the ingot bottoms.

The **top two-way fired pit** is a deep rectangular pit in which the fuel is fired from opposite ends into a combustion space above the ingots (Figure 21-8). The burners are set to fire horizontally at an angle to the centerline of the pit to obtain a swirling motion of the gases. Outlet ports are located in the endwalls just above the cinder line. Long-flame burners are used generally to distribute properly heat from combustion above and between the ingots. The flow of gases is ver-

FIG. 21-7. Schematic diagram showing principle of firing and flow of gases in a side-fired or bottom two-way fired soaking pit. Gases from waste-gas ports go to a recuperator (not shown).

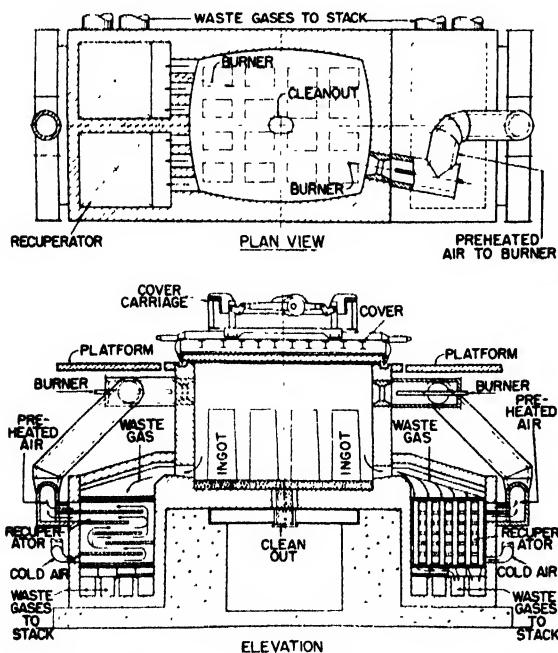

FIG. 21-8. Diagrammatic elevation and plan view of a top two-way-fired soaking pit. Left-hand section of plan view is through waste gas ports; right-hand section through one of the burners. Left-hand half of elevation is section through air passages of recuperator; right-hand, through waste-gas passages. (Courtesy, Amsler-Morton Company.)

tical, similar to that in the one-way fired pits. In this design, the method of firing allows the pit shape to be selected that will give the desired coverage; it may be built long and narrow or square. Curved (elliptical) sides and endwalls, now common to the design of most square and rectangular types of pits, are utilized also in these pits.

Auxiliary Facilities—The principal pit-furnace auxiliaries are pit covers, ingot pit cranes, facilities for ingot delivery to and from the pits and for cinder removal, along with the necessary instrumentation and controls for fuel and air supply and draft regulation.

Pit covers are constructed in various ways, the essential parts being a metal framework to support the refractories and means for quickly removing the cover replacing it upon the pit. In the older pits, the metal framework usually was made of cast iron, and the bricks were slightly arched for support. The covers were supported upon rollers or wheels which moved over tracks, originally by the use of hydraulic cylinders and later by electric motors. A depression in the track permitted the cover to drop, when in position directly over the pit, and seal the pit opening. This design, however, seldom provided a tight seal at all points and leakage of gases caused high cover maintenance. More modern design consists essentially of a heavy steel frame which supports a suspended arch of high-grade firebrick. They are equipped with either self-actuating motors for lifting the cover vertically to free it from the sand seal and then move the cover sideways to the desired pit opening, or with a cover crane to effect similar movements. The cover crane spans a row of pits and serves several. The steel frame of the modern pit cover is protected on its under side by heat-resisting-alloy castings. These castings are provided with a lip which penetrates into the sand seal. The sand seal, located around the periphery of the top of the pit, is a gutter-shaped space filled with sand. The suspended arch of a modern cover usually is backed up with insulation to reduce radiation losses.

Ingot Pit Cranes—In modern plants, the ingots are handled from the ingot delivery cars to the pits and from the pits to the ingot buggy by pit cranes. These cranes are of the conventional electric overhead design except for the trolley and position of the crane cab. Instead of the conventional hoist drum or drums, the trolley consists of the usual track wheels and a frame supporting a vertical housing in which travels a ram equipped at the bottom with mechanically operated tongs. The crane cab is attached to the lower end of the vertical housing and moves with the trolley. This arrangement of the crane cab is to provide maximum vision for the operator in order that the ingots may be placed in proper position in both pits and ingot buggy without damage to either. The modern pit crane also is used to handle coke breeze for bottom making and in many installations for actually making bottom.

Ingot delivery facilities consist usually of a track and ingot buggies. The ingot buggies which deliver the ingots to the pit are the same ones which held the molds for casting at the steel melting shop. The ingots usually are stripped of molds at the stripper, but in some cases where big-end-up ingots are used, the molds are only loosened at the stripper and are later removed by the ingot pit cranes, thus reducing heat losses enroute to pits. The layout of ingot-delivery tracks to avoid crossings and switches which interfere with other plant movements is very important. Minimizing delay in the delivery of ingots from the steelmaking furnace pouring platform through the stripper and the pit furnace building into the pit furnace not only conserves heat

but provides better metallurgical control of quality and less conditioning cost of the mill product.

Mill delivery facilities consist usually of an electrically-operated ingot buggy or pot car which runs directly between the pits and the mill approach table. There are two modern types of ingot buggies. On one type, the contact of the buggy with a cam arrangement at the mill approach table tilts the cradle of the buggy and throws the ingot from its vertical position in the buggy to a horizontal position on the mill approach table. The other type, in order to avoid battering the mill tables with heavy ingots and the necessity of approaching the tables at a high rate of speed to throw the ingot onto the table, is a self-tipping type. This design has a motor for driving the track wheels, for tilting the cradle, and for turning the table rollers which deliver the ingot in a horizontal position to the approach table.

Cinder Removal Facilities—Pit bottoms are made up with coke breeze to a depth of approximately 12 inches to 16 inches. When this breeze becomes burned or contaminated with scale, refractory or other material, it is removed through cinder holes, of which there are usually two, located in the bottom of the pit. In modern practice these holes, provided with gates at the outer end, discharge the cinder into a box located in the cinder alley under the pit bottom. The cinder box often is supported by a lift tractor or car which carries the box through the cinder tunnel to a hoist where it can be lifted to yard level and dumped into broad-gage cars for disposal. Some plants are equipped with an underground narrow-gage track system for moving the car to the cinder hoist. Bottoms for the older pit designs generally are made up each day; in modern pits they are made up only every 5 to 7 days under normal conditions.

Fuel, air and draft facilities of a soaking pit are extremely important as these control furnace temperature and atmosphere. In modern pits the quantity of fuel, the desired fuel-air ratio and the draft or pressure in the pits are controlled automatically. The rate of fuel input is controlled by temperature measurement to maintain some predetermined level. The air is proportioned to the amount of fuel fired at a ratio that will give a slight excess or deficiency of air as desired. The furnace draft or pressure is controlled by automatically raising or lowering the stack damper to maintain the desired furnace draft. Pit-furnace burners are of various designs to provide the type of flame most suitable for heating in each particular pit design. In the regenerative pit the port acts as a burner. Some pit designs utilize a long-flame burner in which the air and gas are not mixed intimately in order to develop slow combustion and a longer path of heat release. In others, the mixing is very rapid and a short non-luminous flame is developed. Some burners are designed to inspire either the gas or air. Low-pressure inspiring burners usually employ gas at a low pressure to inspire air for combustion. With high-pressure inspiring burners, either the gas or air is carried at sufficient pressure to inspire the required volume of the other that is at low or atmospheric pressure. Modern pits are provided with accurate means for measuring and controlling the air volume required for the combustion of fuel. Generally, motor-operated fans are used to supply the air. Fans are used for delivering either hot or cold air to the burners. If recuperators or regenerators are not installed, the fans deliver cold air. Fans may be installed in some designs on either the cold or hot side of the recuperator. If on the cold side, the fan construction is simple and does not require special features such as

alloy blades and an insulated casing, as is the case with hot-air fans. Cold-air fans, however, subject the recuperator to a high pressure differential across its tubes and joints which sometimes causes excessive air losses and lowered recuperator efficiency.

Objectives in Modern Soaking Pit Design—The principal requirements of modern pit furnaces are:

1. Uniform heating of all ingots in the pit with no localized overheating of any ingot.
2. Heating rate equal to the ability of the steel to safely absorb heat.
3. Sufficient holding capacity to accommodate the required number of ingots without overcrowding.
4. Low operating cost.
5. Control of furnace atmosphere.
6. Ability to duplicate heating practices.
7. Minimum expenditure of ground space.
8. Minimum capital expenditure.

The first objective noted above is the most difficult to attain. Many different types of pits have been introduced to solve this problem. Uniform heating of all ingots in a pit with no localized overheating of any ingot permits holding the highest possible temperature in the pit compatible with the ability of the steel to absorb heat without sweating the surface or injuring the steel from severe temperature strain. Optimum heating rates are obtained by holding the surface just below the sweating point. This permits the most rapid flow of heat by conduction into the body of the steel. Since the flow of heat from the surface decreases as the temperature of the center of the ingot rises, the rate of firing must be reduced as heating proceeds to prevent overheating the surface. Variations in firing rate introduce problems in pit furnace heat distribution, as the hottest part of the flame, or the length of travel of heat release of the fuel, changes with fuel volume and air-fuel ratio. Experience with various pit types generally dictates the proper adjustments necessary for variation in firing rate. In some cases alterations in fuel-air ratio or furnace draft are the remedy chosen. In many instances, when heating with regenerative pits, and occasionally with other types, adjustment for lack of uniform temperature distribution is secured by firing at a uniform rate for a period of time followed by a period during which the pit is dampered and no fuel is admitted. During the latter period, the steel is "soaked" to equalize the temperature between ingots in the pit and between the surface and the interior of individual ingots. This practice, known as "firing and dampering," provides a product with a uniform temperature at high production rates even though uneven heating developed during the firing period.

In order to aid uniform heating, circulation of the gases in the pit furnace has been given considerable thought in modern design. Entrainment of cooler, spent gases with the hotter products of combustion, especially near the burner, dampens the tendency of the flame to develop a hot spot, lengthens the time for full release of heat from the fuel and aids in uniform heating. Other effective methods utilized for obtaining uniform temperature distributions are: (1) designing the burner to release the heat of combustion of the fuel over as great an area in the pit as possible to avoid concentration of heat, (2) developing the flame sufficiently distant from the ingot surface to control radiation within safe limits, (3) reducing flame emissivity by using non-luminous-flame type burners or the equivalent, and (4) use of higher pit pressure. A cause of uneven heating in pit furnaces is the fact that the top of an ingot is exposed to heat from all sides while the

bottom rests on a relatively cold unexposed surface. It is necessary to compensate for this either by proper distribution in the flow of gases in the pit, or, as is done in some designs, by maintaining higher effective flame radiation at the pit bottom. In some cases, as noted above, uniform heating is secured only by "soaking." Since the corners of ingots are heated from two adjacent sides, these parts reach the desired temperature first and, therefore, prevent the carrying of an otherwise permissible higher furnace temperature during a considerable part of the heating time.

The modern trend in pit design has been to construct larger holes than the two to six ingot capacity size formerly used. However, the over-all economy of using large pits for small ingots is not favorable for some mills and careful study of cycles is required in the selection of the proper size of pit.

Fuel consumption and the maintenance of modern pits have been reduced considerably by improved design, the installation of automatic controls and better materials of construction. Fuel-air ratio control for combustion and furnace atmosphere have reduced scale losses and the frequency of bottom making. Temperature measurements associated with automatic fuel-input control have made it possible to duplicate heating practices.

Modern Heating Practices—The time required to heat a charge of ingots in soaking pits generally is associated with transit time. The heat content of the ingot when charged into the pit is related to transit time, and it obviously requires less time to heat hotter steel. Transit time is the elapsed time beginning with the "start to pour" of ingots at the steel-producing source and ending with the charging of the first ingot of the heat into the soaking pit. The heating time required for ordinary carbon steels is approximately $1\frac{1}{2}$ times the transit time when the track time is not excessive. Heating cold ingots usually requires from 8 to 12 hours, but, if the ingot is unusually large or of some particular type of steel which requires special treatment, it may require up to 18 hours.

Modern instrumentation has made it possible to estimate the relative state of temperature difference between the surface and center of the ingot from the temperature-time and fuel-input readings. Formerly, the heater, by careful observation of the ingots through sight holes in the cover and his knowledge of temperature requirements for each particular type of steel, determined when the charge was ready for rolling. While this practice is still common with old regenerative-type pits, the heating in continuous-fired pits is governed largely by automatic controls which carry out the heating program desired.

In heating ordinary grades of hot carbon steel in modern pits with automatic control, the operator sets the control dial at the temperature level desired for drawing. A full, or maximum, head of fuel automatically is fired into the pits in the early stages of heating. The fuel input is cut back gradually as the heat soaks into the ingot until it is finally reduced to a minimum, just sufficient to cover pit radiation losses. When the fuel input

has remained at this low level for some specific time, such as a half hour or more, as experience dictates, the ingots are drawn. With high-carbon steel and many alloy grades which are cold or have had a long transit time, it is customary to cool the pit down to the temperature of the charged steel before placing these grades in the pits. They are then brought up rather slowly to some fixed temperature below the rolling temperature. After the ingots have been soaked at this lower temperature, most types of steel may be heated rapidly to rolling temperature. A common practice in heating certain alloy steels is known as **step heating**. Step heating consists in heating ingots to rolling temperature through several levels, each level being held for some specific time to permit equalization of temperature through the ingot. This procedure eliminates stresses due to severe temperature gradients in the ingots and provides slow, uniform heating. With step heating, it is customary to reduce the fuel-rate input considerably below the maximum setting permitted for heating ordinary types of steels. The best practice for heating each type and size of steel may be duplicated with modern control facilities. The fuel-air ratio control affects the flame characteristics and the furnace atmosphere. Flame characteristics have an important bearing on temperature distribution in the pit, and furnace atmosphere affects scale formation and character of the scale. By controlling the furnace atmosphere to advantage, the frequency of bottom making may be reduced, and minor surface defects on the ingot (from cooling, pouring or deoxidation practice) may be corrected or prevented from becoming more serious.

Operating Statistics—The principal operating data, aside from quality of heating and maintenance, relate to production output and fuel consumption. For comparative purposes, production is based generally on "live" pit area since there are so many different sizes and types of pits. The live pit-hole area is the area available in the pits on which ingots can be placed for heating. With proper loading this coverage of live pit area amounts to approximately 35 to 40 per cent (never more than 50 per cent) in modern pits. An average month's practice with modern pits is heating 30 to 100 tons of ingots per hour per 1000 square feet of live pit-hole area. This wide variation is due principally to the temperature at which the ingot is charged and to the type of steel. Other important factors causing the wide spread in pit furnace productivity are differences in the size and length of ingots, irregularity in mill operations and melting-shop pouring schedules, and the portion of live pit area occupied by the ingots.

The amount of fuel consumed per ton of steel heated varies from approximately 300,000 to 2,000,000 Btu. This variation also is due largely to variations in the temperature of the charged steel. Other factors contributing to fuel economy are careful design, proper use of insulation, reduction of stack-gas losses with recuperators and regenerators, proper installation of controls, utilization of the maximum percentage of hearth, controlled metallurgical practices, and regularity of melting shop and rolling-mill schedules.

SECTION 3

REHEATING FURNACES

Furnace Types—Reheating furnaces are divided into two general classes:

1. Batch type.
2. Continuous type.

Batch furnaces are those in which the charged material remains in a fixed position on the hearth until heated to rolling temperature. Continuous furnaces are those in which the charged material moves through the

FIG. 21-9. Schematic longitudinal section through a recuperative batch-type reheating furnace. (Courtesy, Amsler-Morton Company.)

furnace and is heated to rolling temperature as it progresses through the furnace. Batch furnaces are the older type and are used for heating all grades and sizes of steel. However, small billets seldom have been heated in this type since the introduction of continuous furnaces. Batch furnaces are fired with either gaseous or liquid fuel, with preheated or cold air for combustion. The air may be preheated by regenerators and the furnace firing reversed from one end to the other, as in open-hearth furnaces. Batch furnaces, in which the air is preheated by recuperators, are not reversed and firing is continuous from one or both ends, depending upon the location of the gas outlet port (Figure 21-9). The steel to be heated in a batch furnace commonly is charged and drawn through front doors by a charging machine. Batch furnaces vary in size from those with hearths of only a few square feet, with a single access door, to those twenty feet in depth by fifty feet long, with five or six doors.

Continuous furnaces were designed initially for heating billets and small bloom sections. The hearths were relatively short in length and were sloped downward longitudinally towards the discharge end to permit an easy movement of billets through the furnace. In early designs, the furnaces were fired by burners located at the discharge end and the billets were heated by the hot gases flowing through the furnace above the top surface of the steel toward the charging end. Pushers were used to push forward the charge of cold billets. The flow of gas and steel in the furnace were counter-current. The modern continuous furnace has been altered in many respects from those of early design, although a large number of the older ones, particularly billet-heating furnaces, are still used. Longer furnaces generally are constructed now. Some have hearths 80 to 90 feet long, with top and bottom firing, and contain preheating, heating and soaking zones. The hearths usually are constructed level. A transition from the early designs to the modern three-zone slab heating furnace is illustrated in Figure 21-10.

The steel to be heated in a continuous furnace can be

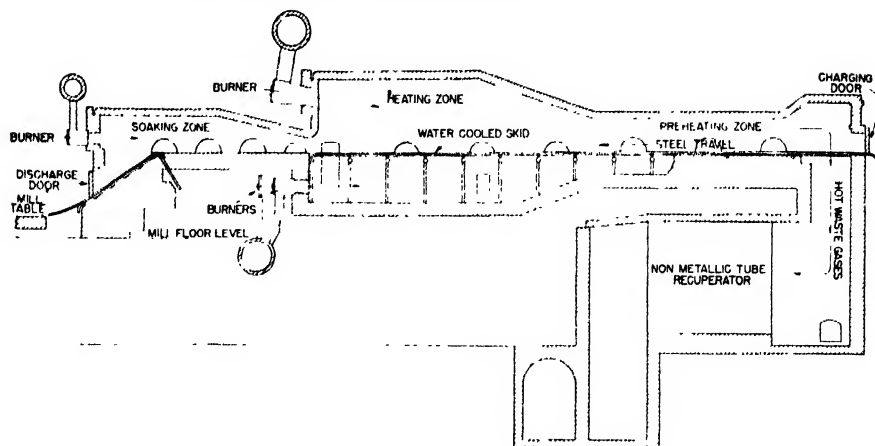

FIG. 21-10. Diagrammatic steps in the evolution of the modern three-zone slab-heating furnace from earlier designs.

FIG. 21-11. Schematic longitudinal section through a counter-current fired continuous reheating furnace. (Courtesy, Rust Furnace Company.)

charged either from the end or through a side door. In either case, the steel is moved through the furnace by pushing the last piece charged with a pusher at the charging end. As each cold piece is pushed into the furnace against the continuous line of material, a heated piece is removed. The heated piece is discharged either through an end door by gravity upon a roller table which feeds the mill, or it is pushed through a side door to the mill table by suitable manual or mechanical means. Figures 21-11 and 21-12 show sections through modern furnaces using counter-current and co-current flow of gases and steel, respectively.

A distinctly different type of continuous reheating furnace is the rotary-hearth type, a cross-section of which is shown schematically in Figure 21-13. It is used frequently for heating rounds in tube mills and for heating short lengths of blooms or billets for forging. The rotary-hearth type permits the external walls and roof to remain stationary while the hearth section of the furnace revolves.

General Considerations in Furnace-Type Selection—Some of the particular advantages of batch-type furnaces are:

1. They provide means for heating steels of various types and sizes, which can be heated more properly in separate batches than when mixed with other types in the same furnace, especially when specific heating practices are required.

2. They are suitable as a reservoir for holding hot steel directly from the primary mill for later rolling in the finishing mills.

3. They can be operated to heat steel to temperatures above 2400° F more satisfactorily than a continuous furnace. Steel can be given a "wash heat," when desirable, without trouble from the pieces sticking together. (Steel is sometimes "washed" or heated until an earlier oxide scale is melted and a new scale formed, to reduce surface defects.)

4. They provide excellent means for soaking steel.

Some of the important disadvantages of batch furnaces are:

1. High capital investment per unit of production.

2. Low hearth area efficiency. That is, the hearth in the conventional type is not utilized fully because of interference of door jams and clearance required inside the furnace for handling the stock with charging machines.

3. High man-hours per ton of heated steel.

4. Lack of flexibility for heating steel slowly in the lower temperature range. Furnaces must be cooled to charge high-carbon steel and some alloy steels.

5. Length of pieces to be heated is limited by tendency to bend when they are removed.

The advantages of the conventional continuous-type furnaces are:

1. High production per dollar of investment.

2. Low man-hours per ton of steel heated.

3. Greater ease in charging and drawing steel.

4. High hearth area efficiency.

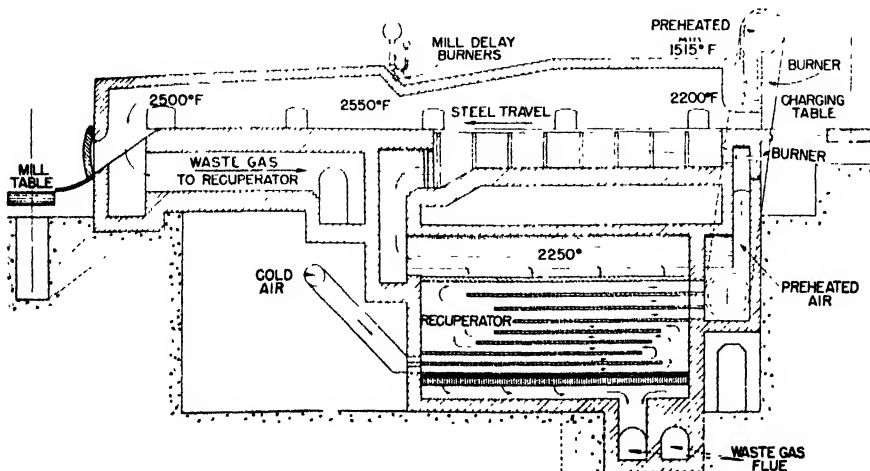

FIG. 21-12. Schematic longitudinal section through a co-current fired continuous reheating furnace. (Courtesy, Amsler Morton Company.)

FIG. 21—13. Schematic arrangement of a relatively-small continuous rotary-hearth heating furnace. The plan view (above) shows a section above the hearth near the bottom of the baffle. Larger furnaces of this type have burners firing through both inside and outside walls above the hearth. (Adapted from a Salem Engineering Company drawing.)

5. Better means for controlling the rate of heating at all temperature levels. Gradual rise in temperature permits charging all grades of cold steel without cooling furnace.

6. Less trouble from temperature inequalities between each succeeding piece drawn.

7. High production per square foot of ground space occupied.

8. Can be built for any reasonable length of piece to be heated, resulting in higher mill yield, because of fewer crop ends from lengths beyond batch-furnace possibilities.

Some of the important disadvantages of conventional continuous furnaces are:

1. Lack of flexibility for heating efficiently small orders of different lots of steel or thicknesses. Heating time must be increased to suit the heating cycle of the piece, requiring lower heat transfer rate which may be detrimental to the heating of the other grades and sizes in the furnace.

2. Trouble from water-cooled skid maintenance, and from building up of scale on hearth, which results in piling of steel in furnace, due to climbing of pieces over each other, because of lack of square contact between adjacent pieces, when pressure is applied by the pusher.

3. Face of contacting surface of stock must be square to prevent piling.

4. Expensive to empty furnace at end of schedule.

5. Difficulty in pushing mixed sizes through furnace.

FIG. 21-14. Barrel-type furnaces in tandem for continuous reheating of pierced seamless tubes for sizing. Conveyor rolls between adjacent furnaces support the work in its travel. Temperatures are automatically controlled by radiation-type pyrometers.

Some of the important advantages of rotary-hearth furnaces are:

1. They eliminate either the manual labor required for rolling rounds forward on horizontal or moderately sloped hearths, or the disadvantages of excessively sloped hearths in continuous furnaces.

2. They have better means for controlling the rate of heating at all temperature levels than batch-type furnaces.

Some of the important disadvantages of the rotary-hearth furnace are:

1. High capital cost per unit of production.
2. Low hearth area efficiency.

3. Large ground space required per unit of production.

Some features in both batch and conventional continuous furnaces are worthy of note:

1. Regenerators or recuperators act as a reservoir of heat supply, which is especially valuable for efficient soaking of steel.

2. Continuous furnaces provided only with top firing require longer hearths for equal production than those with top and bottom firing, but do not require a special soaking zone to eliminate cold spots on the work caused by contact with water-cooled skids. Heating of sizes greater than 4 inches thick is not economical in furnaces that are top-fired only.

3. Continuous furnaces with single-zone firing have higher scale losses and greater tendency to cause decarburization of high-carbon steel than the top-and-bottom fired furnaces, since the steel is in the furnace longer. Decarburization is caused primarily by hydrogen and water vapor combinations in furnace gases, and increases almost directly with the time the steel is at elevated temperatures. Free air and carbon dioxide in the furnace atmosphere cause decarburization to a lesser degree. The scaling of steel is practiced sometimes deliberately to remove the decarburized surface layer.

4. A level hearth in a continuous furnace eliminates the stack effect of hearths sloping upwards towards the charging end. This stack effect draws cold air into the furnaces at the hot end causing higher fuel consumption and scale losses.

5. Batch-type furnaces used for heating in a production line require supplementary furnaces for preheating certain grades of alloy and high-carbon steels for transfer into the hotter furnaces. The preheating zone of a continuous furnace makes this unnecessary.

6. Back-fired or continuous furnaces with co-current flow of steel and gases subject the steel in the charging end to rapid surface heating which is not suitable for heating steels that have low thermal diffusivity, such as high-carbon and heat-resisting alloys. (Thermal diffusivity is equal to the thermal conductivity divided by the product of mass specific heat times density.) This type of furnace provides well-soaked heating for mild and medium-carbon grades of steel.

7. Side-discharge continuous furnaces have less air infiltration at the hot end than end-door discharge furnaces. End-door discharge of the usual gravity type induces cold air into the furnace by the stack effect at the discharge section of the furnace. End-door discharge, however, is mechanically simpler for removing the heated stock, particularly slabs and heavy blooms.

Furnaces have been developed to raise the temperature of steel for hot shaping by exposing the piece to be heated to intense radiant energy from gas burners of special design, set very close to the path of the steel. This method of heating has been very effective in obtaining fast heating for small round sections. The barrel-type furnaces in tandem shown in Figure 21—14 are used for reheating pierced tubes for sizing in seamless-tube mills. This method has recently been applied to soaking pits.

The trend in reheating furnace design is towards the continuous type, with increased attention to refinements to satisfy conditions pertinent to each mill or forge shop, or the types of steel being heated.

Operating Statistics—The production rate of furnaces varies widely. Batch furnaces, as a general class, produce much less tonnage per furnace operating hour than the continuous type. While batch furnaces often are used for heating hot charges, as in structural and rail mills, continuous furnaces usually are used only for heating cold steel. Batch furnaces heating cold charges for rolling mills are designed to heat from 5 or 6 tons up to 25 tons per furnace hour. When heating a hot charge, the production is much higher, and the rate depends largely upon the temperature of the charged material and the size of the furnace.

The production of a continuous furnace depends principally upon the hearth size of the furnace and whether the material is heated from more than one side. Many

continuous furnaces heat over 50 tons of steel per furnace hour. A modern three-zone slab-heating continuous furnace, 20 feet wide, with an effective hearth length of 80 feet, top and bottom fired, is capable of heating 110 tons of slabs per hour to a rolling temperature of 2250° F. The productive rate of a furnace for a fixed thickness of steel is directly proportional to the surface exposed to the flame, other conditions remaining the same. For comparison of furnace performance, the relative number of pounds heated per effective square foot of hearth area per hour is used as a common factor. By this comparison, furnaces heat from 30 to 150 pounds per square foot of hearth area per furnace hour. The variation in heating capacity is due principally to the difference in the total surface of the steel exposed to heat in the furnace, which the hearth area does not measure. Other factors are the temperature of the heated product and the grade of steel. In many batch furnaces, the material receives heat from three sides and in continuous furnaces from two sides. Heating from more than one side decreases heating time and, therefore, increases production rates. The production and fuel rates of furnaces are affected by continuity of operation. A furnace will not provide high production rates and fuel economy if it is operated for only short intermittent periods. It also must be fully loaded to provide optimum production and fuel economy.

The fuel consumption of reheating furnaces varies from 300,000 to 3,000,000 Btu per ton. When hot steel is heated, very little additional heat may be required to attain rolling temperature. If the steel charged is at a temperature of 1800° F, only about 140,000 Btu per ton must be added in the furnace to heat to 2250°, while with cold steel about 700,000 Btu must be added in the furnace. If the hot steel requires 500,000 Btu per ton input to the furnace and only 140,000 Btu are absorbed,

the furnace fuel efficiency is $\frac{140,000}{500,000} \times 100$, or 28 per cent.

If cold steel is heated with a fuel consumption of 2,000,000 Btu per ton, as obtained in many modern furnaces,

the furnace fuel efficiency is about $\frac{700,000}{2,000,000} \times 100 = 35$

per cent. The best fuel efficiency is obtained in continuous furnaces that are relatively long, have hearths fully covered with steel, and are operated at a high rate of continuity. In both batch and continuous furnaces, the length of gas travel and the velocity of the gases through the furnace have an important effect on fuel economy. An excessive velocity of furnace gases tends to increase the exit temperature of the gases leaving the furnace and, therefore, low fuel efficiency results. Fuel efficiency is improved by providing features in design that reduce the inherent furnace losses. The greatest losses usually are represented by the heat carried away in the stack gases. Reduction of this loss can be obtained by the installation of recuperators, regenerators or waste-heat boilers, and by designing the furnace cross-sectional area for proper gas velocities. Automatic fuel-air ratio and furnace-pressure control reduce stack losses by reducing the volume of gases from excess air for combustion, or from air infiltration. Radiation losses are reduced by insulation of the furnace walls, roof and hearth. Losses from water-cooled skids in continuous furnaces can be reduced by eliminating any unnecessary exposure of them to hot furnace gases, and to some extent by use of refractory pipe covering.

SECTION 4

HEAT-TREATING FURNACES

General Design Requirements—Heat-treating furnaces are grouped into either batch or continuous furnaces. There are many different types in each group. The simplest furnaces are the direct-fired batch type with manual controls. The more elaborate installations used for large production lines are continuous furnaces with automatic program control. In a number of installations, special facilities for controlling the atmosphere in the working chamber are provided to obtain the desired surface condition. The most common heat treatments performed in furnaces are annealing, normalizing, spheroidizing, hardening, tempering, carburizing and stress relieving. Heat-treating furnaces seldom are designed for temperatures in excess of 2000° F, and generally are operated in the 800° F to 1600° F range. They are usually well insulated and built tight to prevent air infiltration or a loss of special atmosphere gas. Attention in design is directed toward procuring uniform temperature distribution in the working chamber of the furnace. The position and method of heat application, and the circulation of gases in the furnace, are of major consequence in this. In annealing furnaces, means for controlling both the rate of heating and cooling of the stock usually are provided. Since the required heating and cooling rates of different types of steel vary, it is necessary to provide flexible means for controlling these functions. Insulating firebrick is used generally in heat-treating furnace construction, due to its low heat-storage capacity, to permit heating and cooling the furnace quickly. For intermittent furnace operation this is particularly vital. Attention is directed in design to spacing the charge in order to attain the most efficient flow of heat around the stock. In coil-annealing furnaces, and in furnaces for heat treating other material, special facilities often are provided to improve the circulation of special atmosphere gases during heating and cooling. In all heat-treating layouts, special consideration is given to providing sufficient furnace capacity to maintain the desired time-temperature relation of the treatment. Furnaces forced beyond their normal capacity usually yield an erratic and non-uniform product.

For handling batch loads of material to be heated, quenched, and tempered, quench tanks and cranes should be located in such a way that little time is lost in getting the material from the furnace into the quenching medium. Furnaces also must be arranged so that, after quenching, a second furnace is available for taking the charge promptly for further treatment. Usually three furnaces are provided for operations of this type: two for heating and one for tempering.

In large-scale heat-treating operations, the layout of facilities is very important. The furnaces must be arranged to suit an orderly flow of material through the shop. Adequate space for temporary storage and handling is necessary for both the raw and the finished material. A sufficient number of cranes or other stock-handling facilities of the proper capacity must be provided to eliminate bottlenecks or interference with prescribed furnace cycles. A central station for the preparation of atmosphere gas generally is provided in the larger furnace layouts where particular attention to steel surface is required.

In heat-treating furnaces, many furnace parts, such as conveyors or rollers in continuous furnaces, radiant tubes for indirect firing and covers in coil and pack-

annealing furnaces, are of metallic construction since the temperature seldom exceeds the 800° to 1600° F range. Special alloy materials are utilized to reduce the maintenance of these parts to a minimum. In selecting the furnaces for a heat-treating plant, careful consideration must be given to the type of product to be heated, to the kind of treatment to be performed, and to the production rate required. The ensuing sections explain pertinent factors in design and describe the application of various furnace types.

Method of Heat Application—The character of the material to be heated and the type of treatment to be performed have an important bearing on the choice of method of heat application. Heat-transfer laws govern the flow of heat to the steel in heat-treating as in other heating furnaces. The surface of the material absorbs heat transmitted to it by radiation or by convection or both, and this heat is transferred through the body of the material by conduction. In heat-treating furnaces, the transfer of heat by convection is relatively more significant than in furnaces operated at a higher temperature level. In heat treating steel, the rate of heat transfer to the surface is usually low in order that each individual piece, as well as all pieces in the furnace, may be brought up uniformly to the required temperature level. However, in some furnaces which utilize induction heating or radiant-type open-flame burners, uniform

heating can be accomplished rapidly with high heat-transfer rates.

Gaseous fuel and electric power are the two main sources of heat used in heat-treating furnaces. In some cases, fuel oil has been substituted for gas due to a shortage of the latter or for economic reasons. In gas heating, a number of variations in method of firing are used. These variations may be separated into two general classes, direct and indirect firing. Direct firing is used more generally. This method permits the products of combustion of the fuel to circulate about the material to be heated. In direct-fired furnaces, open burners may be used either in the furnace proper or they may be installed outside the work-heating chamber in the path of an external fan which circulates large volumes of hot gases through the furnace. Temperatures attainable in this type of furnace are limited by the materials of which the fan is constructed. The latter modification is used in convection-type furnaces. In indirect-fired furnaces the products of combustion do not enter the work-heating chamber. Indirect firing is used in muffle furnaces, an example of which is shown in Figure 21—15.

Another common application of indirect firing is ob-

tained with radiant tubes, an example of which is shown in the furnace in Figure 21—16. Furnaces using direct firing are relatively lower in operating cost and original capital investment. Furnaces using indirect firing generally are selected where the control of furnace atmosphere is of particular importance.

Electric power is used as a source of heat in many heat-treating furnaces due to the ease it affords for controlling temperature, to its suitability for use with protective-gas atmospheres, and to its cleanliness. Resistance-type heating elements, which either are imbedded in the furnace refractory lining or suspended from heat-resisting hangers, radiate heat to the furnace charge. The resistance units are positioned in the furnace to permit uniform heating. Furnaces with zone heating sometimes use electrical resistance units because of their easy adaptation to the control of temperature levels. Another method for heating electrically is by induction. Induction heating is done by passing a high-frequency alternating current through a coil surrounding the material to be heated. The coils are shaped to suit the material to be heated. The rapidly alternating electrical field, in which the material to be heated is held, causes the steel to heat very rapidly, due to eddy

currents and hysteresis. Due to the rapidity of the process, the duration of heating is very critical, necessitating precise control.

Atmosphere Control.—The effect of a heat-treating operation on the surface condition of the work pieces is influenced by the time of heating, the temperature level maintained, and the atmosphere surrounding the material. Figure 21—17 shows graphically the relative amount of scale formed in a batch reheating furnace for variations of these conditions. While the temperature level in heat-treating furnaces is somewhat lower than that shown in the figure, the time is generally longer. By using the proper atmosphere in the working chamber, a clean scale-free surface is obtained. Such a surface is required for most sheet and strip material and other important steel products, such as wire and tubes. The three gases most injurious to surface condition are oxygen, carbon dioxide, and water vapor. The effect of each of these, as well as effects from other gases, follows:

Oxygen reacts with the iron of the steel to produce iron oxide. For this reason it must be excluded entirely for bright annealing. It also reacts with the carbon in steel to lower the carbon content of its surface; that is, it decarburizes the steel. In some types of controlled annealing, oxygen of the air may be caused to scale the steel faster than it decarburizes it. This results in a

product having a decarburized surface layer of minimum thickness and the scale, being flaky, is easily removed.

Nitrogen, in the molecular state, is entirely passive to iron and is entirely satisfactory for bright annealing low-carbon steels. If pure and very dry, it will be passive to high-carbon steel, but the presence of even slight traces of moisture will cause decarburization.

Carbon dioxide and carbon monoxide are considered together since the ratio of their concentration in the atmosphere plays an important part in their action on the steel surface. As an example, if the ratio of carbon dioxide to carbon monoxide is 0.6 or higher at 1500° F, the atmosphere will scale steel readily. If the ratio is reduced to 0.4, or lower, the atmosphere will no longer scale steel but will remain decarburizing to a 1 per cent carbon steel. For low-carbon steels, a ratio of carbon monoxide to carbon dioxide on the order of about two to one will be in equilibrium with the steel, and a gas of this composition is used to advantage for producing bright-annealed sheets. A higher carbon-monoxide content actually will carburize the steel.

Hydrogen is highly reducing to iron oxide, and, therefore, opposes the formation of a heavy, flaky scale and when present in the products of combustion, promotes formation of a tight scale that is hard to remove. At certain temperatures it is absorbed by the steel and is likely to result in embrittlement, more particularly in high-carbon steel. If the hydrogen is dry, it has no scaling effect on high-carbon steel at elevated temperatures, but it does cause considerable decarburization. A common prepared atmosphere which is used for bright-annealing work is composed of 75 per cent hydrogen and 25 per cent nitrogen. It is formed by cracking anhydrous ammonia. Hydrogen is highly explosive if mixed with air and particular precaution must be exercised to prevent air infiltration into furnaces in which it is employed.

Water vapor is oxidizing to iron and combines with carbon of steel to form carbon monoxide and hydrogen within the temperature range of the "water-gas reaction." It is reactive to a steel surface at temperatures even as low as 400 to 700° F, and is thus often the cause of formation of a blue oxide during the cooling cycle.

Hydrocarbons, more specifically methane, are carburizing gases. They are subject to thermal decomposition at annealing temperature, liberating hydrogen and depositing soot on the steel.

The most commonly prepared gases for control of atmosphere are formed by the partial combustion of hydrocarbon gases, contained in such fuels as coke-oven gas, natural gas, propane, or butane. Manufacturers of converters for the preparation of gases describe the various kinds under trade names, such as "DX" gas, "Drycolene," etc. The first step in making such a gas is to burn a mixture of the fuel gas with air. This provides a gas high in nitrogen, but containing other undesirable gases including water vapor, which must be removed. Other atmosphere gases are prepared by (1) cracking a non-combustible mixture of air and gas with a catalyst at high temperature, (2) by cracking anhydrous ammonia at high temperature, and (3) by passing air through a heated retort filled with charcoal.

Furnaces using controlled atmosphere have a number of construction features not incorporated in ordinary furnaces. These features are essential to prevent loss of gas and to minimize the entrance of air into the furnace which would upset the control established. Casings for furnaces with controlled atmosphere are welded gas-tight. Batch-type furnaces are provided with sand seals. Continuous furnaces charged and discharged from the

ends sometimes have flame curtains to burn out the oxygen from any possible air infiltration, or the furnace may be operated under sufficient pressure to prevent air infiltration. In the latter case, a small loss of the prepared atmosphere usually occurs through the small unavoidable openings in the furnace. Doors, where required, are fitted snugly by sloping fronts with ground surfaces or by wedging devices or clamps.

Batch-Type Furnaces—The five principal general types of batch furnaces are described below:

1. **Box furnaces** are constructed with a solid hearth. They are shaped, as their name implies, similar to a box and are charged through door openings by tongs or some mechanical charger. The furnace hearth may vary from a few square feet in area to over 30 square feet. Heating may be done by direct or indirect fuel firing or by electricity. Muffle and semimuffle type construction often is employed when control of atmosphere is required. This type of furnace is used frequently for individual-piece or small-lot heat treating, for laboratory test and shop work, and for general production work on a small scale. Box furnaces have been constructed for convection heating either with a fan underneath the roof or with one external to the furnace for recirculation. Furnaces of this type are used for annealing, normalizing, tempering and carburizing.

2. **The car-bottom furnace** consists of a furnace shell equipped with burners or heating units with the hearth built upon a separate car which runs in and out of the furnace shell to charge and unload the furnace. The car usually is moved into and out of the furnace by a toothed rack attached to the bottom of the car and a stationary pinion actuated by an electric motor, the car itself resting on rollers or wheels that move over a two-rail track. The doors of the furnace are of the vertically

lifting type, full width of the furnace, and are hydraulically or electrically operated. In order that the entire surface of the charge may be exposed to heat of the same intensity and to aid circulation, the charge is supported above the floor of the car bottom by heat-resisting alloy castings or on refractory piers. The car bottom is made to fit the furnace closely and the escape of hot gases around it is prevented by sand seals. Car-bottom furnaces have been constructed to process charges from a few tons to several hundred tons. They are used for heat treating of axles, bars, heavy plates, castings and miscellaneous shapes.

For operations involving heating, quenching and tempering, it is desirable that the quenching tank be located in proximity to the furnace to enable the charge to be placed in the tank in the shortest possible time. In some installations, less than a minute is required to transfer the charge from a closed furnace to the quenching tank. Car-bottom furnaces may be direct or indirect fired, and various designs have been developed to improve heat distribution in the working chamber. Electric heating also is employed in some car-bottom furnaces. Car-bottom furnaces sometimes are constructed of two chambers side by side, with a common division wall to facilitate annealing and tempering operations. In some installations, an auxiliary cooling system employing blowers is provided to accelerate cooling. Some car-bottom furnaces are known as **elevator furnaces** where the car is rolled under the furnace shell and then raised into the furnace by a motor-driven lifting mechanism. Those in which the shell is lowered over the car, as shown in Figure 21—18, are used to provide a more complete sand or water seal than is obtainable with the conventional car-bottom furnaces.

3. **The bell-type furnace** has a removable shell or
